Abstract

Tin titanate (SnTiO₃) has been notoriously impossible to prepare as a thin-film ferroelectric, probably because high-temperature annealing converts much of the Sn²⁺ to Sn⁴⁺. In the present paper, we show two things: first, perovskite phase SnTiO₃ can be prepared by ALD directly onto p-type Si substrates; and second, these films exhibit ferroelectric switching at room temperature, with p-type Si acting as electrodes. X-ray diffraction (XRD) measurements reveal that the film is single-phase, preferred-orientation ferroelectric perovskite SnTiO₃. Our films showed well-saturated, square and repeatable hysteresis loops of around 3 μC/cm² remnant polarization at room temperature, as detected by out-of-plane polarization versus electric field (P-E) and field cycling measurements. Furthermore, photovoltaic and photoferroelectricity were found in Pt/SnTiO₃/Si/SnTiO₃/Pt heterostructures, of which properties can be tuned through band gap engineering by strain according to the first-principles calculations. This is a new lead-free room-temperature ferroelectric oxide of potential device application.
I. INTRODUCTION

SnTiO$_3$ has been predicted to be a room-temperature ferroelectric with large polarization [1-3]. However, it has been difficult or impossible to process [4]. The Cambridge group found that only ilmenite formed [4], and in general, high-temperature processing and annealing may convert most of the Sn$^{2+}$ to Sn$^{4+}$. Therefore, we studied its production via low-temperature ALD [5].

We emphasize that unlike ferromagnetism, ferroelectricity is not strictly a property of a material but of a system consisting of a dielectric and electrodes. In order to demonstrate switching it may be necessary, for example, to have blocking electrodes rather than ohmic, in order to minimize leakage currents and obtain useful hysteresis curves. In the present case, we demonstrate switching for SnTiO$_3$ directly on conducting p-type Si, which acts as both substrate and electrode. Si electrodes were first used in ferroelectric thin-film devices by the IBM San Jose group in the 1970s [6], and they are well understood. The main difference compared with metal electrodes is the longer screening length for depolarization fields [7].

There are known artifacts that can look like ferroelectric switching: L. Pintilie and M. Alexe [8] have shown that back to back diodes produce a polarization versus voltage P-V hysteresis curve that closely resembles true ferroelectricity. However, there are two ways to discriminate unambiguously between such artifacts and true ferroelectric switching hysteresis. First, artifacts consisting of charge injection have hysteresis curves that move clockwise with time [9], which is impossible for true ferroelectric hysteresis; and second, back-to-back diodes (for example, the Si/SnTiO$_3$ interfaces in our systems) will not exhibit a Curie temperature above which hysteresis disappears. In the present work, we demonstrate
both of these requirements (counterclockwise hysteresis and a measured Curie temperature) to prove true ferroelectricity at room temperature.

There is no reason to be skeptical of the present results on SnTiO$_3$ synthesis, since both the XRD and SEM [5] measurements closely match those reported previously from powder data [10, 11], which showed 100-nm diameter single-phase nanocrystals with $T_C = 628$ K (close to the frequency-dependent relaxor $T_C = 600$ K we measure). However, the earlier work was not commercially viable, since it requires a highly-toxic TiCl$_4$ precursor. Moreover, Sn$^{2+}$ in the powder prepared, due to disproportionation to Sn$^{4+}$ and metallic Sn, might not easily survive the sintering process requisite to make pellets or films for devices.

It has been reported that SnTiO$_3$ has an optical band gap lying in the visible region of $\sim 2$ eV or even lower, which makes it a good candidate for photo-ferroelectric materials [12, 13]. Photo-ferroelectric materials are particularly interesting due to coupling between photosensitivity and ferroelectric properties, which provide a large possibility of optoelectronics and solar energy harvesting applications [14-18]. However, there are very few useful photo-ferroelectric materials because most ferroelectrics have wide optical band gaps ($> 3$ eV). Therefore, experimental values of the direct optical band gap in SnTiO$_3$ thin films were also compared with theoretical values calculated from density functional theory (DFT). We have observed photo-ferroelectricity and a photovoltaic effect in our Pt/SnTiO$_3$/p-Si/SnTiO$_3$/Pt capacitor structures.
II. METHODS

A. Experimental details

SnTiO₃ thin films of 40 nm thickness were deposited on p-Si substrates (p-type Si (100) substrates (resistivity: 1-10 Ω·cm, 20 × 20 mm²)) using atomic layer deposition (ALD) technique as detailed in reference [5]. Pt top electrodes were deposited on ALD-grown SnTiO₃ thin films using RF-magnetron sputtering technique. X-ray diffraction (XRD) was performed with a PANalytical Empyrean diffractometer operating in reflection mode using monochromated Cu Kα₁ radiation. XRD data was collected from 2θ values of 10 to 120 degrees with step size of 0.017 degrees. Total data collection time was 90 minutes. Macroscopic ferroelectric properties were investigated with a ferroelectric loop tester (TF Analyzer 2000, aix-ACCT). To examine the intrinsic fatigue behavior, 10 µs wide electric pulses with a frequency of 10 kHz were applied to the Pt-top electrode. An incandescent lamp was used as a source to measure light-induced changes in ferroelectric hysteresis loops. Photovoltaic measurements were performed using a Keithley-2401 electrometer under 1-sun AM 1.5 solar simulator with light source density ~1 kW/m². Conduction mechanisms in Pt/SnTiO₃/p-Si/SnTiO₃/Pt capacitors were studied through current-voltage (I-V) measurements using a Keithley 2401 source-meter unit. Temperature dependent measurements were done using a programmable Joule-Thompson thermal stage system (MMR model # K-20). Dielectric measurements between frequencies 500 Hz and 300 kHz were done using an impedance analyzer HP4924A. M-2000 ellipsometer (J. A. Woollam Co.) employed to record two ellipsometric parameters, ψ and δ, of SnTiO₃ film on p-type Si substrate. Then a two-layer model composed of the substrate and film was used to determine
the optical constants of the films. The optical constants of the substrate as well as film thickness were obtained separately and fixed during the fitting procedure.

**B. Theoretical methods**

A computational study was conducted to evaluate the bandgap of the polar perovskite SnTiO$_3$ subjected to epitaxial strain following the approach outlined in reference [12]. DFT [19, 20] calculations were performed using the Vienna ab initio Simulation Package (VASP) [21, 22] within the local density approximation (LDA), parameterized by Perdew and Zunger [23]. The projector-augmented plane-wave method [24, 25] simulated the core and valence electrons. A plane-wave basis supporting the wave function cutoff at 900 eV was used to converge the total energy of the system to within 1 meV/f.u. Zone-edge-shifted $8\times8\times8$ Monkhorst-Pack (MP) [26] k-point mesh was used for the Brillouin zone (BZ) integration. Force components on individual ions were relaxed to less than 1 meV/Å and stress-tensor components on the simulation cell to less than 0.1 kbar in all the structures studied. The monoclinic angle ($\beta$) was not allowed to relax in the monoclinic $\text{Cm}$ phase. The biaxial misfit strain was defined as $\varepsilon = \frac{a}{a_0} - 1$, where $a_0$ corresponds to the optimized lattice parameter of the cubic $\text{Pm\bar{3}m}$ structure with all the normal stresses relaxed to values less than 0.1 kbar. It is well known that LDA exchange correlation functional underestimates the value of band gap. We have therefore computed more accurate values of the perovskite SnTiO$_3$ band gaps using the Heyd-Scuseria-Ernzerhof (HSE) screened hybrid functional [27].
III. RESULTS AND DISCUSSION

X-ray diffraction (XRD) measurements were carried out to study the structural characteristics of our thin films. XRD patterns recorded at ambient conditions showed that the film is single-phase, preferred-orientation ferroelectric perovskite SnTiO₃ (Figure S1). Based on the XRD data, we can predict that our films have grains with several orientations of (101), (011), (211), and (100) with c/a ratios of 1.144, 1.146, 1.036 and 1.061, respectively (see Supplemental Material) [28, 29].

Polarization-electric field (P-E) hysteresis loop measurements were done on Pt/SnTiO₃/p-Si/SnTiO₃/Pt capacitors at different applied voltages, as shown in Fig. 1 (a). Inset of Fig. 1 (b) represents the schematic of Pt/SnTiO₃/p-Si/SnTiO₃/Pt capacitor structure used for ferroelectric and photovoltaic measurements. P-E hysteresis loops in Fig. 1 (a) clearly indicate the presence of room temperature ferroelectricity with a well-defined remnant polarization and coercive field. The saturated (Pₛ) and remnant polarization (Pᵣ) values were found to be around ~7.5 µC/cm² and 3.3 µC/cm², respectively, at room temperature and 40 kHz frequency.

From Fig. 1 (a), a clear hysteresis switching current characteristic with a nest of loops, one inside the other were observed with increasing applied voltages. The inset of Figure 1(a) displays the direction of the hysteresis curve as a function of time, which is counterclockwise and thus excludes the possibility of artifacts consisting of charge injection, which sometimes mimic ferroelectric-like behavior [9]. Some preliminary work on ferroelectric hysteresis was also done in an earlier report [5]. They switched via an AFM tip and obtained very reproducible fully saturated switching loops at a coercive field of 4 V across 40 nm. This value of E_c = 100 MV/m is very reasonable for perovskite oxides and compares with about
20 MV/m in the present work. The present data are better than those of earlier work [5], because we have a parallel-plate capacitor structure and can therefore estimate electroded area, whereas no quantitative value of polarization could be obtained from the AFM-tip switched data of the earlier work. Perhaps most important in the present context, the hysteresis data of earlier work [5] are on an asymmetric Si/SnTiO$\text{\textsubscript{3}}$/AFM-tip geometry and not on a Si/SnTiO$\text{\textsubscript{3}}$/Si symmetric sandwich. Therefore, the hysteresis data cannot arise from a back-to-back diode artifact, as discussed by Pintillie and Alexe [8]. We have also measured capacitance-voltage curves on single metal-oxide-semiconductor (MOS, Pt/SnTiO$\text{\textsubscript{3}}$/Si) and two back-to-back connected MOS (Pt/SnTiO$\text{\textsubscript{3}}$/Si/SnTiO$\text{\textsubscript{3}}$/Pt) based capacitor structures of SnTiO$_3$ film (see Supplemental Material, Fig. S2) [28, 30-32], where the presence of two capacitance peaks attests to the fact that we are observing ferroelectric switching even in the MOS structure [30-32]. More interestingly, we observed the presence of two capacitance peaks (maxima) in more symmetric way for the case of two back to back connected MOS structure, revealing a true ferroelectric property of our SnTiO$_3$ films.

Moreover, to exclude any possibility of charge injection and electret effect due to trapped charges at the Si/SnTiO$_3$ interface, we measured the frequency dependence of P-E hysteresis loops as shown in Figure 1 (c). Frequency dependence of P-E hysteresis loop illustrates clear polarization switching at higher frequencies (up to 80 kHz). Such frequency dependent behavior eliminates the possibility of a back-to-back diode effect, where the response at such high frequencies is not feasible for electrets since slow motion of ions is required. In addition, temperature dependent P-E hysteresis loop and polarization measurement using PUND technique were also performed to confirm the ferroelectric nature of our thin film as shown in Fig S3 (see Supplemental Material) [28].
In Figure 1(c), a drastic change in $P_r$ values from low ($\leq 20$ kHz) to high ($\geq 40$ kHz) frequencies was observed whereas there was little change in $P_s$ (the extrapolated value at $E=0$ axis) as a function of frequency. The internal bias field created at each MOS structure will tend to stabilize polarization with opposite direction (see Figure 1(b)) due to their back-back connection. As such, at low frequency, our Pt/SnTiO$_3$/Si/SnTiO$_3$/Pt structure will suffer from backswitching phenomena resulting in very low net remnant polarization. However, at high frequency, the depletion will not play a significant role, so there will be negligible backswitching phenomena in the structure, resulting in high remnant polarization. We speculate that this is why we see a drastic change in $P_r$ in a stepwise fashion from 20 kHz to 40 kHz, while we see small change in $P_s$ as a function of frequency in Figure 1(c).

Temperature dependent current ($I$) versus voltage ($V$) curves were measured from 83 to 600 K to understand the electrical conduction mechanism in Pt/SnTiO$_3$/p-Si/SnTiO$_3$/Pt capacitors as shown in Fig. 2 (a). To reveal the dominant conduction mechanism of charge transport, the temperature dependent I-V curves were plotted on a logarithmic scale, as shown in Fig. 2 (b-c). As can be seen from Fig. 2 (c), the logarithmic I-V plot at room temperature can be fitted into three regimes, where the low and intermediate regimes are thought to arise from Ohmic conduction and Child’s square law, respectively, and the high-voltage region corresponds to a steep increase in current [33]. Based on such I-V behavior, the conduction mechanism in our films is likely to be trap-assisted space charge limited current conduction [34]. However, it has often been observed in oxide thin films that a linear I-V relation at low applied voltages can also be explained by Simmons’ modified Schottky emission mechanism. Unambiguous discrimination of these mechanisms will require thickness-dependent current measurements for further clarification [35]. At present, however,
the temperature dependence of current can be used to determine the depth of the trapping levels. The slope of \( \ln I \) versus \( 1/T \), which is \((E_c-E_t)/k\), provides the activation energy value, as shown in Fig. 2 (d). We found that deep trap levels exist in the film with activation energy of \( 1.3\pm0.1 \) eV. This value is reasonable for oxygen-vacancy transport in perovskite oxides, including SrTiO\(_3\), where 1.1 eV is the most common value [36, 37]. This value is found in two ways: From the \( \ln I \) vs. \((1000/T)\) graph in Fig. 2 (d) and, less precisely, as the kink and steep increase in current of the \( \ln I \) versus \( \ln V \) curve in Fig. 2 (c) near \( \ln V = 0 \) (i.e., \( V = 1 \) V).

It is important to rule out charge injection as a source of artifacts. In addition to noting that the polarization hysteresis loops are saturated, we provide in Fig. 3 data showing a dielectric peak at \( T_C = 450 \) 600 K, depending upon probe frequency from ca. 500 Hz to 300 kHz. These data display the signature of a relaxor ferroelectric and satisfy a Vogel-Fulcher relationship with an extrapolated freezing temperature of ca. 452 K (Fig. 3b), suggesting local disordering of the Sn-ions. Inset of Fig. 3 (b) shows the relationship between dielectric constant and temperature near freezing temperature, which is described by modified Curie-Weiss law [38]. A plausible hypothesis for the observed glassy behavior is the presence of some Sn\(^{4+}\) at the Ti\(^{4+}\) perovskite B-site. This could be tested via XPS measurement of the Sn\(^{4+}/Sn^{2+}\) ratio. Since all these temperatures are well above ambient, these properties do not detract from the potential for commercial devices. Parenthetically, the Vogel-Fulcher behavior also helps rule out any artifacts as explanations of the hysteresis curves discussed above.

We have also observed the photovoltaic effect in Pt/SnTiO\(_3\)/p-Si/SnTiO\(_3\)/Pt capacitors. In the dark, a very small current \( (10^{-4} \mu A) \) at zero bias voltage could be detected. Under white
light illumination a distinct photovoltaic behavior was observed with short circuit current (J_{SC}) = 3 \mu A and open circuit voltage (V_{OC}) = 0.13 V, as shown in Fig. 4 (a). V_{OC} and J_{SC} were measured as a function of time over multiple on/off light cycles, showing good retention over time, with instability in V_{OC} and J_{SC} displaying a sudden increase and then return to initial values, as shown in Fig. 4 (b). To explain the unstable nature of J_{SC} in multiple light on/off cycles, we measured the variation in J_{SC} under continuous light illumination of 120 seconds, as shown in Fig. S4 (see Supplemental Material) [28]. We observed a continuous increase in photocurrent under continuous light illumination, which could be attributed to the presence of trap levels due to the structural defects, mainly oxygen vacancies [39, 40]. Under the light illumination, photo-generated electrons are transferred to the conduction band and some of them occupy the deep trap levels. Photocurrent starts increasing slowly as the trap levels are filled gradually. In addition, we have also observed photosensitivity of our samples in the ultraviolet (UV) region. The photovoltaic behavior of SnTiO_{3} films under UV-light illumination has been shown in Fig. S5 (see Supplemental Material) [28, 41]. There may be a small effect of the Si substrate on the photovoltaic effect but very limited as the photovoltaic effect from the Si/SnTiO_{3} interfaces will be cancelled out due to the nature of back to back connection, and only the ferroelectric part will contribute to the photovoltaic effect as the ferroelectric polarization will be aligned in the direction from one Pt electrode to the other Pt electrode. To further confirm the contribution from Si substrate, we measured I-V curves under the illumination of a red laser pen (~650 nm) and we observed a negligible contribution from Si in overall photovoltaic effect (see Supplemental Material, Fig. S6) [28].
Moreover, polarization fatigue, which is an important factor to determine the switchability of remnant polarization over the field cycles, was also measured with 10 µs wide electric pulses at a frequency of 10 kHz. Figure 4 (c) shows the evolution of remnant polarization of SnTiO$_3$ as a function of switching cycles. We confirmed nearly fatigue-resistant characteristic up to $10^6$ cycles in our SnTiO$_3$ capacitor, which is comparable to early studies of Pt/Pb(Zr,Ti)O$_3$/Pt capacitors [42]. Interestingly, we have also observed photoferroelectric effect in Pt/SnTiO$_3$/p-Si/SnTiO$_3$/Pt capacitor structures, where enhancement in ferroelectric properties was observed with an increase in $P_s$ and $P_r$ values under white light illumination. Such enhanced ferroelectric behavior shows the photo-ferroelectric nature of SnTiO$_3$ thin films.

A combination of experimental and computational techniques was utilized to evaluate the optical band gap of SnTiO$_3$. We measured the refractive indices of the film samples, $n$ and $k$, using spectroscopic ellipsometry technique and calculated absorption coefficient, $\alpha$. The (direct) band gap was determined to be 2.6 eV by linearly extrapolating $(\alpha E)^2$ versus photon energy ($E$), as indicated by a gray line in Fig. 5 (a) [43].

In such oxides strain imposed by substrates could be an important factor to tailor the band gap. Electronic properties of perovskite SnTiO$_3$, including band gap values, band structure and electronic density of states (EDOS), were investigated for varying epitaxial strain $\varepsilon$. Figure 5 (b)-(d) shows an electronic band dispersion diagram (left panel) and EDOS (right panel) of SnTiO$_3$ obtained within the local density approximation (LDA) for (b) $\varepsilon = -0.33\%$, (c) $\varepsilon = 0\%$ and (d) $\varepsilon = +0.33\%$, i.e., throughout the region where a transition from $P4mm$ to $Cm$ structure accompanied by a large band gap change was predicted by the previous investigation [12]. The band gap remains indirect (from X to $\Gamma'$) for all the
considered strains, with value changing from ~0.5 (compression) to 1.0 eV (tension), as previously reported [12]. We also included ion and \( l \) quantum-number-resolved EDOS for the aforementioned three epitaxial strain states. Valence bands between 16 and 17 eV are composed of Sn \( s \) and O \( p \) states. Conduction bands between 19 and 21 eV are largely composed of Ti \( d \) states with a small mixture of O \( p \) states. It is well known that LDA exchange correlation functional underestimates the value of the band gap. We computed more accurate values of the perovskite SnTiO\(_3\) band gaps using the Heyd-Scuseria-Ernzerhof (HSE) screened hybrid functional (see Supplemental Material, Fig. S7) [28], obtaining values of 2.175 eV for the \( P4mm \) phase under compressive and zero strains, and 2.655 eV for the \( Cm \) phase stabilized in epitaxial tension. The band gap value predicted by the HSE-based calculation for the monoclinic \( Cm \) phase is in a close agreement with the one determined by the experimental techniques, although at this point the nature of the band gap is not clear, since the experiment data point toward a direct band gap while the theory suggests an indirect band gap. The plot of strain dependent band gap based on EDOS suggests that we need to enhance tensile strain inside SnTiO\(_3\) film to further lower the optical band gap, which will enhance the photoferroelectric property of the film (see Supplemental Material, Fig. S7) [28].

**IV. CONCLUSION**

In summary, we demonstrated room temperature relaxor ferroelectricity and photovoltaic effects in SnTiO\(_3\) thin films deposited directly on the p-type Si substrates. XRD data, polarization-electric field hysteresis loop and permittivity measurements, dependence of dielectric peaks at \( T_C = 450-600 \) K on probe frequency from ca. 500 Hz to 300 kHz, and a
Vogel-Fulcher relationship with an extrapolated freezing temperature of ca. 452 K, confirm the presence of relaxor ferroelectric perovskite SnTiO₃ in our films. Furthermore, photovoltaic and photoferroelectricity were manifested in Pt/SnTiO₃/Si/SnTiO₃/Pt heterostructures, of which properties can be tuned through optical band gap engineering by strain according to the first-principles calculations. This study provides a path to develop green material for various ferroelectric and dielectric based emerging nanoelectronic devices and photoferroelectric applications.
