### 1 Abstract:

2 Both immune profiling and tumor budding significantly correlate with colorectal cancer (CRC) patient outcome, but are traditionally reported independently. This study evaluated the 3 association and interaction between lymphocytic infiltration and tumor budding, coregistered 4 on a single slide, in order to determine a more precise prognostic algorithm for patients with 5 stage II CRC. Multiplexed immunofluorescence and automated image analysis were used for 6 the quantification of CD3<sup>+</sup>CD8<sup>+</sup> T cells, and tumor buds (TBs), across whole slide images of 7 three independent cohorts (training cohort: n = 114, validation cohort 1: n = 56, validation 8 cohort 2: n = 62). Machine learning algorithms were used for feature selection and prognostic 9 10 risk model development. High numbers of TBs (HR = 5.899, 95% CI, 1.875 - 18.55), low  $CD3^+$  T cell density (HR = 9.964, 95% CI 3.156 - 31.46), and low mean number of 11  $CD3^{+}CD8^{+}$  T cells within 50 µm of TBs (HR = 8.907, 95% CI 2.834 - 28.0) were associated 12 with reduced disease-specific survival. A prognostic signature, derived from integrating TBs, 13 lymphocyte infiltration, and their spatial relationship, reported a more significant cohort 14 stratification (HR = 18.75, 95% CI 6.46–54.43), than TBs, Immunoscore, or pT stage. This 15 was confirmed in two independent validation cohorts (HR = 12.27, 95% CI 3.524-42.73, HR 16 = 15.61, 95% CI 4.692-51.91). The investigation of the spatial relationship between 17 lymphocytes and TBs within the tumor microenvironment improves accuracy of prognosis of 18 patients with stage II CRC through an automated image analysis and machine learning 19 workflow. 20

### 1 Introduction:

2 Tumor Node Metastasis (TNM) staging remains the gold standard for stratification of 3 colorectal cancer (CRC) patients into prognostic subgroups, and is fundamental for treatment selection (1,2). Surgical resection without the use of adjuvant treatment results in long-term 4 disease-free survival in most stage II CRC cases. However, 20% of patients experience 5 disease-specific death (3). In addition, some stage III patients experience better outcomes 6 than some stage II patients. This is in spite of revisions to the TNM guidelines, which, for 7 example, subdivide pT stage II into three categories (4). Alongside pT stage, tumor 8 differentiation aids the pathologist in sub-stratifying patients into high or low risk of tumor 9 progression; however grade is highly subjective (5). Tumor budding, which morphologically 10 resembles small, poorly-differentiated clusters of cells (1-4 cells) disseminating at the 11 invasive margin, has consistently been correlated with poor CRC prognosis (6-8). 12

Both TNM staging and tumor budding concentrate solely on the tumor, but it is now well 13 established that the host interaction, such as immune infiltrate, within the tumor 14 microenvironment (TME) plays a crucial role in tumor progression (9,10). Specifically, in 15 CRC, the pioneering studies of Galon and colleagues demonstrated that CD3<sup>+</sup> and CD8<sup>+</sup> T-16 cell infiltration was an independent prognostic factor predicting patient survival (9,11). 17 Tumor buds (TBs) are hypothesized to represent a highly invasive tumor subpopulation, 18 especially if they also have the ability to evade the host immune response (6-8). The 19 interaction between immune response and TBs may therefore hold vital information 20 pertaining to the tumor's potential to metastasize. 21

Previous research has demonstrated the ability to automatically quantify CD3<sup>+</sup> and CD8<sup>+</sup> T 22 cells within the TME, thereby achieving a greater level of standardization than with 23 subjective, manual reporting (9). Similarly we have previously shown that tumor budding can 24 be standardized through automated image analysis (12,13). Although the automatic 25 quantification of both immune infiltrate and tumor budding has been associated with patient 26 prognosis, they have not been studied together. Furthermore, by coregistration on the same 27 tissue section it is possible to accurately study the spatial interaction with each other. We 28 apply such an approach in this study to investigate if quantifying both features alongside their 29 spatial interaction allows for a more precise and accurate prognosis for stage II CRC patients. 30

### **1** Materials and methods

#### 2 Patient Material and Clinical Data

This study included three independent cohorts of stage II CRC patients who underwent 3 surgical resection in Edinburgh, UK, hospitals over the years 2002-2004 (n = 170) and the 4 National Defense Medical College Hospital (NDMCH), Japan, over the years 2006-2011(n =5 62). The formalin-fixed paraffin-embedded (FFPE) block that contained the deepest cancer 6 7 invasion for each patient was selected after the review of hematoxylin and eosin (H&E) slides. Cancer blocks from Edinburgh hospitals comprised specimens of cross-sectional cut 8 whereas the ones from the NDMCH were of longitudinal cut. Associated clinical data 9 included features from the original pathology report, such as TNM staging and differentiation 10 as well as detailed follow-up information including disease specific survival (DSS); up to 11 11.5 years for the Edinburgh cohort and 8.6 years for the Japanese cohort. 114 consecutive 12 patients who underwent surgical resection in Edinburgh hospitals over the years 2002-2003 13 were used as a training cohort for this study. All available patients who underwent surgical 14 resection in Edinburgh hospitals in the following year (2004) were used as a first validation 15 cohort (n = 56). We then used a similar number of patients who underwent surgical resection 16 in the NDMCH, Japan over the years 2006–2011 as an international validation set (n = 62). 17 The clinicopathological data of all the cohorts are shown in Table 1. This study was 18 19 conducted in accordance with the declaration of Helsinki. Ethical approval was obtained after review by the NHS Lothian NRS BioResource, REC-approved Research Tissue Bank (REC 20 approval ref: 13/ES/0126), granted by East of Scotland Research Ethics Service and by the 21 Ethics Committee of the National Defense Medical College (approval ref: No.2992). The 22 ethical approval permitted us to use archival diagnostic samples once they were de-identified 23 for the purposes of the research. 24

25

#### 26 Immunofluorescence and Image Capture

#### 27 <u>Immunohistochemistry antibody optimization</u>

We selected externally validated specific primary antibodies: primary antibody against CD8<sup>+</sup> 28 cytotoxic T cells (monoclonal mouse anti-human CD8, M7103, Dako, Glostrup, DK) was 29 previously used for the international validation of the consensus Immunoscore by Pages et 30 primary antibody against pan T cells (Polyclonal Rabbit Anti-Human CD3, 31 al.(14), A045201-2, Dako, Glostrup, DK) used by Harter et al. (15), in assessment of tumor-32 infiltrating lymphocytes in human brain metastases and for pan-cytokeratin (PanCK) (mouse 33 monoclonal anti-human cytokeratin, M351501-2, Dako, Glostrup, DK) previously used by 34 35 Koelzer et al. (16), for the assessment of TBs in CRC.

In order to assess the in-house antibody performance, each antibody was individually 36 assessed by brightfield immunohistochemistry (IHC). The primary antibodies against CD3 37 and CD8 T cells were each tested individually on 3µm thick serial sections of normal tonsil 38 FFPE tissue, known to have high lymphocytic cell concentration. For assessment of PanCK 39 primary antibody, a CRC optimizing tissue microarray, consisting of 100 cores taken from 40 primary tissue blocks, was used. Expression of all cell markers was detected using 3,3'-41 Diaminobenzidine (DAB) chromogen (K3468, Dako, Glostrup, DK). Nuclei were 42 counterstained with hematoxylin (RBA-4213-00A, CellPath, Newton, UK). In parallel, H&E 43

(RBB-0100-00A, CellPath, Newton, UK) staining was performed on serial sections and specificity of antibodies from the IHC was assessed and compared visually by an experienced pathologist (DJH) and research scientists (IPN and PDC). No CD8 positive but CD3 negative cells were present, giving confidence to the antibodies' specificity. Positive and negative controls were used in each immunohistochemistry staining; human tonsil FFPE tissue without primary antibody for CD3 and CD8 T cells and a CRC optimizing tissue microarray without primary antibody for PanCK. Western blot analysis was also used to assess the specificity of

8 the PanCK antibody using CRC cell lines.

#### 9 <u>Immunofluorescence staining optimisation</u>

Once specificity of antibodies was confirmed in brightfield, each target was assessed by a 10 uniplex immunofluorescence. Uniplex immunofluorescence was performed on serial sections 11 of the CRC optimising tissue microarray (specified above) with the use of individual 12 tyramide signal amplification (TSA) fluorescence kits. After deparaffinization, slides were 13 placed in a microwaveable pressure cooker containing boiling antigen retrieval (AR) buffer 14 (0.1M Sodium Citrate pH6) and microwaved for 5 min at 75 °C. Slides were allowed to cool 15 down in running tap water for 20min at room temperature and were then rinsed with 0.1% 16 Phosphate buffered saline-Tween 20 (PBS-T). PBS-T was used for all washing steps. Tissues 17 were then blocked with 3% hydrogen peroxide for 5 minutes and Dako serum free protein 18 block (X090930-2, Dako, Glostrup, DK) was then applied for 10 minutes. Slides were then 19 incubated for 30 min with the same antibodies as for immunohistochemistry at these 20 dilutions: CD3 (dilution 1:400), CD8 (dilution 1:200) and PanCK (dilution 1:100). Slides 21 were then washed (3 x 5min). The slides that had previously been incubated with CD3 or 22 CD8 antibodies were then incubated in pre-diluted anti mouse or anti rabbit HRP conjugated 23 secondary antibodies (K400111-2 and K400311-2 respectively, Dako, Glostrup, Denmark) 24 for 30 min. Following 3 more washes of 5 min, slides were incubated for 10 min with either 25 TSA® fluorescein (FITC) for CD3 antibody visualisation or TSA® Cyanine 5 for CD8 26 antibody visualisation (NEL741B001KT and NEL745B001KT respectively, Perkin Elmer, 27 MA, USA) at 1:100 dilution. The slide that had been previously incubated with PanCK 28 antibody was then incubated in anti-mouse AlexaFluor 555 (A21422, ThermoFisher, MA, 29 USA) in antibody diluent (S080983-2, Dako, Glostrup, DK) at 1:100 dilution for 30 min. 30 Finally, following a washing step, the slides were counterstained for 10 min with Hoechst 31 33342 (H3570, ThermoFisher, MA, USA) at 1:20 dilution in de-ionised water. Sections were 32 then dehydrated in 80% ethanol and mounted with ProLong Gold Antifade Reagent (P36930, 33 34 Thermo Fisher Scientific Inc., MA, USA). Optimal antibody dilutions in the uniplex immunofluorescence slides were chosen to ensure best signal to noise and specific staining 35 pattern when digitised on the Zeiss Axioscan.z1 whole slide scanner (Zeiss, Oberkochen, 36 DE). Fluorescence slides were compared with serial section of brightfield DAB slides using 37 38 the same antibodies. Positive and negative controls were included in each staining run. The positive controls for the CD3 and CD8 antibodies were the tonsil tissue as specified above. 39

Once the appropriate dilution of primary antibodies, secondary antibodies and fluorophores 40 were found under uniplex immunofluorescence, we then assessed them multi-plexed on a 41 single tissue section. In order to eliminate species cross reactivity, microwave stripping was 42 performed between the CD8 and PanCK staining. Microwave stripping was performed as 43 follows. AR buffer was heated in a pressure cooker in the microwave for 12 min prior to 44 45 adding the slides in the solution. Slides were then microwaved for 17 min using the auto defrost function. Sections were then allowed to cool down in running tap water for 20 min 46 and washed for 5 min. The immunofluorescence protocol utilised to label the study samples 47 was performed as above using a DAKO Link48 Autostainer (Dako, Glostrup, DK). The first 48

- 1 run of labelling included the primary antibody against CD8 prior to antibody stripping, and
- 2 labelling with a primary antibody cocktail of CD3 and PanCK prior to counterstaining with
- 3 Hoechst. The multi-plexed section was compared to the uniplex labelled serial sections and
- 4 we confirmed that there was no increase or decrease in the level of specific signals or
- 5 nonspecific background signals.
- 6 Whole slide fluorescence images were captured with a 20x objective using an Axioscan.Z1
- 7 (Zeiss, Oberkochen, DE). Exposure times for Hoechst, Cy3, Cy5 and FITC channels were 12,
- 8 120, 8 and 25ms, respectively (see supplementary methods for detailed protocol of antibody
- 9 optimization and multiplexed immunofluorescence).
- 10

### 11 Digital Image Analysis

- 12 Digital whole slide fluorescence images, in Zeiss' .czi file format, were uploaded into HALO
- 13 Next Generation Image Analysis software (version 2.1.1637.18) (IndicaLabs, Corrales, NM)
- 14 for image analysis. Full algorithm workflow and settings are shown below:
- 15
- 16 <u>Nuclear segmentation:</u>

All nuclei in the whole slide image were automatically segmented using the commercially available High-Plex FL (version 2.0) module within the HALO Next Generation image analysis software. Optimized module parameters for nuclei detection included dye weights (Hoechst nucleus weight = 4, Cy5 nucleus weight = 0.232, FITC nucleus weight = 0.232), nuclear contrast threshold (0.5), minimum nuclear intensity (0.079), nuclear segmentation aggressiveness (0.65) and using the default nuclear size setting (1-500 $\mu$ m<sup>2</sup>). All samples were analyzed using these specific settings.

- 24
- 25 <u>Lymphocytic Infiltration Analysis</u>

Within the same software module in which we segmented the nuclei, (High-Plex FL), cells 26 were then classified as CD3 (FITC) or CD8 (Cy5) positive based on dye nucleus positive 27 threshold (Cy5 = 0.132, FITC = 0.15), cytoplasm positive threshold (Cy5 = 0.075, FITC = 28 0.5) and membrane positive threshold (Cy5 = 0.075, FITC = 0.5). The algorithm settings 29 were kept constant across all patients. Next, the algorithm automatically quantified the 30 number of each lymphocyte classification across the whole slide image. The flood tool was 31 used to identify the invasive front. An invasive margin (IM) was created which consisted of a 32 width span of 500µm in and out from the invasive front. The tumor core area (CT) was set to 33 be the whole tumor area excluding the 500µm before the invasive front (Fig. 1A). 34 Lymphocytes (CD3<sup>+</sup> and CD8<sup>+</sup> T cells) infiltrating both the CT and the IM of the tumor were 35 automatically quantified (Fig. 1B) and their densities (cells/ mm<sup>2</sup>) were exported to assess 36 37 their prognostic significance.

- 38
- 39 Immunoscore Evaluation
- 40 Immunoscore was performed based on the methodology described previously by Galon et
- 41 al(9). Using the lymphocytic infiltration analysis results, CD3<sup>+</sup> and CD8<sup>+</sup> lymphocytes were
- 42 counted in both the IM and CT resulting in the reporting of the following features:  $CD3^+T$
- 43 cells in the CT,  $CD3^+$  T cells in the IM,  $CD8^+$  cells in the CT and  $CD8^+$  T cells in the IM.
- 44 Optimal cutoff points for the four features were calculated based on survival data of the

training cohort (Supplementary Table S1). Values above the optimal cutoff points for each feature were scored 1 whereas values below were scored 0. An immunoscore was then calculated by the sum of all scores for each patient sample. Finally, similarly to Liu et al. (17), patients were stratified into two groups; High Immunoscore > 2 and Low Immunoscore < 2.

6

### 7 <u>Tumor Budding Analysis</u>

The PanCK intensity within each whole slide image was initially assessed using the Area 8 Quantification FL v1.2 module without any changes to the commercially available module 9 thresholds. Patient samples were grouped into two categories based on their resulting PanCK 10 intensity; low (average dye intensity  $< 2.16 \times 10^{-2}$ ) and high (average dye intensity  $> 2.16 \times 10^{-2}$ ) 11  $10^{-2}$ ). Using samples from within each PanCK group (high or low), machine learning 12 classifiers were trained to segment tumor from non-tumor region. Two High Plex FL (version 13 2.0) modules were next created; one using the classifier trained from low PanCK patient 14 samples and one from the high PanCK patient samples. Patients with an average PanCK 15 intensity below 2.16-02 were analyzed to segment tumor from non-tumor using the classifier 16 termed 'low PanCK' and the other with the classifier termed 'high PanCK'. These modules 17 were run within a 1000µm border inwards from the invasive front; termed the tumor budding 18 region of interest (TBROI) (Fig. 1C). Within the tumor regions detected, nuclei were detected 19 using the methodology described above and cancer cells were classified based on PanCK 20 positivity in nucleus (0.1), cytoplasm (0.08) and membrane (0.05) (Fig. 1D). These cancer 21 cell classification thresholds were kept constant across the entire cohort of images. TBs were 22 classified as tumor clusters containing up to 4 PanCK<sup>+</sup> cells. TB density (TBs / mm<sup>2</sup>) and 23 number were then exported from the algorithm. Mucin pools and areas of necrosis were 24 25 excluded.

26

#### 27 Spatial Analysis of Lymphocytes and Tumor Buds

Spatial coordinates of the lymphocytes and TBs were imported into a spatial plot within the 28 HALO software. From this plot, the Spatial Analysis algorithm was utilized to calculate the 29 number of  $CD3^+$  and  $CD8^+$  T cells within a range between 0-100  $\mu$ m radii of TBs (Fig. 1E) in 30 consecutively increasing 10 µm steps therefore creating 11 classes; 0-10 µm, 0-20 µm, 0-30 31 32 µm and so on. All classes of radius size were significantly associated with survival, however after assessing the prognostic significance of iterative groupings of varying radius sizes, there 33 was a statistical difference observed between the 0-50 µm and the 0-100 µm groupings. The 34 classes were therefore merged into two categories: 0-50 µm and 0-100 µm radii of TBs. 35 Finally, the number and densities of CD3<sup>+</sup> and CD8<sup>+</sup> T cells within these distances were 36 established. 37

38

All features exported from the image analysis are listed in Supplementary Table S2.

40

#### 41 Statistical Analysis

All statistical analysis, unless otherwise stated, was performed in RStudio 1.1.419 running R
3.4.3 (18,19). Continuous image analysis data, categorical clinical data and survival data
were loaded into R. The relationship between lymphocyte distribution patterns, TBs, and

patient characteristics was assessed using the Chi-Square test. For comparison with 1 categorical patient data, image analysis features were divided into low and high groups 2 according to optimal cut-off points based on survival data. To assess the relationship between 3 4 lymphocytes and TBs, Spearman correlation coefficients (r) were applied on continuous data. All r = 0 values indicated no association between features, r > 0 indicated a positive 5 association where as one variable increases, so does the other and r < 0 indicated a negative 6 association where as one variable increases the other decreases. Associations between 7 features were assessed on the training cohort. 8

9 Univariate Cox regression was performed on both the categorical clinical and continuous
 10 image analysis data. All P < 0.05 values were considered statistically significant.</li>

The least absolute shrinkage and selection operator (LASSO) penalized Cox proportional 11 hazard regression was performed for identification of significant features (20), using the 12 13 glmnet package (21). The significant features identified by LASSO were then inputted into a 14 random forest (RF) (n = 500) decision tree model using the randomForest package (22) and were ranked according to their mean decrease Gini coefficient. Features with a mean decrease 15 Gini of above 4 were taken forward for further analysis. Optimal cutoff points for these 4 16 features were calculated and iterative combinations of these features were tested. The model 17 with most predictive value was then selected; termed the "tumor bud-immuno spatial index" 18 (TBISI). In order to avoid overfitting during the development of the model, validation was 19 performed for both LASSO Cox regression model (10-fold cross validation) and random 20 forest (out of the bag). Univariate Cox regression was performed for; the TBISI, pT stage, TB 21 number and Immunoscore, and a bootstrap resampling technique was applied (number of 22 samples = 1000) in SPSS 24 (23). Multivariate Cox Regression with a forward stepwise 23 method and the Receiver Operating Characteristic (ROC) curve were also applied on to 24 compare the TBISI, pT stage TB number and Immunoscore in SPSS 24. The prognostic value 25 of TBISI was then assessed on two independent validation cohorts. All validations were 26 performed using the fixed optimal cut-off points of the training cohort. All optimal cutoff 27 28 points for the categorization of image analysis features including tumor budding, the immunoscore and for the development of the TBISI were based on disease specific survival 29 and were calculated using the survminer package (24). All Kaplan Meier (KM) curves were 30 plotted using the survival package (25). The P values from KM curves were corrected for 31 false discovery rate (FDR) using the Benjamini-Hochberg procedure to account for multiple 32

33 hypothesis testing (26).

34 Study workflow is illustrated in Supplementary Fig. S1.

### 1 **Results**

### 2 **Patient Characteristics**

The clinicopathological characteristics of all three cohorts of stage II CRC patients are shown 3 in Table 1. This study cohort comprised a training cohort of 114 stage II CRC patients, of 4 which 57 were female and 57 were male. The validation cohorts included 34 male and 22 5 female patients in validation cohort 1 and 42 male and 20 female patients in validation cohort 6 7 2. The range of patients' age was 37-96 years old. There were 43 right-sided colon carcinomas, 38 left-sided and 33 rectal cancers in the training cohort and 29 and 14 right-8 sided colon carcinomas, 9 and 22 left-sided and 18 and 26 rectal cancers in validation cohort 9 1 and 2, respectively. 10

### 11 Correlations of Patient Characteristics with Lymphocyte Density and TB Number

12 Automated image analysis was performed to quantify TBs (within TBROI), CD3<sup>+</sup> cell, and

- 13 CD8<sup>+</sup> T-cell densities (within IM and CT). Optimal cutoff points based on survival data were
- 14 used to categorize image analysis features of the training cohort into low and high groups
- 15 (Supplementary Table S1). TB number and density were highly correlated with each other
- 16 (correlation coefficient = 0.7466; P <  $2.2 \times 10^{-16}$ ; therefore, TB number was selected to be
- 17 used for correlation assessments. The relationship between patient characteristics and both
- 18 lymphocyte distribution patterns and TB number was then assessed. A high density of  $CD3^+$ 19 T cells at the IM was associated with no extramural lymphovascular invasion (EMLVI; P =
- $10^{-11}$   $1^{$
- mucinous histological type (P = 0.007 and P = 0.023, respectively). A high density of CD8<sup>+</sup>
- 22 cells at the IM and across the whole tumor section (WTS) was significantly associated with
- female gender (P = 0.016 and P = 0.030 respectively). Finally, advanced pT stage was
- significantly associated with a high TB number at the TBROI (P = 0.031) (Table 2).

### 25 Relationship between Tumor Budding and Lymphocyte Density

TB number was tested for association with lymphocyte densities of the training cohort, using the Spearman correlation coefficient (Fig. 2). This indicated a weak negative relationship between TB number and all lymphocytic cell densities (r < 0) regardless of distribution pattern (ie. IM, CT, WTS) or lymphocytic cell subpopulations (CD3<sup>+</sup> or CD8<sup>+</sup>). However, a higher density of CD3<sup>+</sup> T cells at the IM, CD8<sup>+</sup> T cells at the IM, and WTS were significantly correlated with a lower TB number (P = 0.016, P = 0.037, and P = 0.041 respectively) (Supplementary Table S3).

### 33 Survival Analysis - Clinicopathological Data

34 To assess the prognostic significance of the categorical clinicopathological data of the training cohort, univariate Cox-regression was applied. KM survival analysis was used to 35 further assess any significant prognostic features from the clinicopathological data of the 36 training cohort (Fig. 3). Univariate Cox-regression showed that only pT stage (HR =4.143; 37 95% CI, 1.480-11.570; P = 0.006) was significantly associated with disease specific survival 38 (Table 1). KM survival function was then applied and showed that patients of T4 stage have 39 poor DSS (73% survived) compared to T3 stage patients (91% survived) (P = 0.003) (Fig. 40 41 3A).

#### **1** Survival Analysis - Image Analysis Features

To explore the prognostic effects of the quantified lymphocytic distribution patterns, TB 2 3 number and density within the training cohort, we performed univariate Cox-regression analysis. This analysis was also performed for the spatial relationships between lymphocytes 4 5 and TBs. The following specific continuous features were calculated and exported from the image analysis algorithm: a) in IM, CT and WTS; densities of CD3<sup>+</sup> and CD8<sup>+</sup> T cells and 6 ratio of CD3<sup>+</sup> to CD8<sup>+</sup> T cells; b) TB number and density at the TBROI, c) within 0–50 µm 7 and 0–100 µm radius of TBs; number and mean number of CD3<sup>+</sup> and CD8<sup>+</sup> T cells. The 8 densities of both CD3<sup>+</sup> and CD8<sup>+</sup> T cells were significantly associated with disease specific 9 survival (P < 0.05). TB number and density conferred prognostic significance (HR =1.001; 10 95% CI, 1.000–1.001; P = 0.0004 and HR =1.030; 95% CI, 1.000–1.060; P = 0.044611 respectively). KM analysis showed TB number to be a significant prognostic factor; 95% of 12 patients in the low tumor budding group survived compared to the high tumor budding group, 13 in which 73% of patients survived (P = 0.0006) (Fig. 3D). Furthermore, a high mean number 14 of lymphocytes near TBs was significant in predicting disease specific survival for stage II 15 CRC patients (P < 0.05) (Supplementary Table S2). 16

### 17 Significant Feature Selection

All clinicopathological and image analysis data of the training cohort (listed in 18 Supplementary Table S2) were input for a LASSO penalized Cox proportional hazard 19 regression. This was performed to identify the features that add significant value to the 20 prediction of disease specific survival over time and therefore to reduce the data 21 dimensionality. The analysis reported that there were 8 significant candidate features (CD3<sup>+</sup> 22 T-cell density at WTS, mean CD3<sup>+</sup>CD8<sup>+</sup> T-cell number within 0–50 µm of TBs, TB Number, 23 CD8<sup>+</sup> T-cell density in CT, pT stage, EMLVI, age, and differentiation). The 8 features which 24 added value to the model were used as further input into a RF decision tree model for optimal 25 26 prognostic feature selection. The RF model reported 4 features with a mean decrease Gini of above 4 (CD3<sup>+</sup> T-cell density in WTS, mean CD3<sup>+</sup>CD8<sup>+</sup> T-cell number within 0-50 µm of 27 TBs, TB number, CD8<sup>+</sup> T-cell density in CT) (Table 3). 28

#### 29 Development of Tumor Bud Immuno-Spatial Index

30 Optimal cutoff points for these 4 features (CD3<sup>+</sup> T-cell density in WTS, mean CD3<sup>+</sup>CD8<sup>+</sup> Tcell number within 0–50 µm of TBs, TB number, CD8<sup>+</sup> T-cell density in CT) were calculated 31 for the training cohort using the patient survival data (389.6 cells/mm<sup>2</sup>, 4.1, 1104.0, and 114.7 32 cells/mm<sup>2</sup>, respectively). The least significant feature was then removed in an iterative 33 process until the removal of a feature decreased the prognostic value of the model. This led to 34 the creation of the TBISI consisting of 3 features; CD3<sup>+</sup> T-cell density in WTS, mean 35 CD3<sup>+</sup>CD8<sup>+</sup> T-cell number within 0–50 µm of TBs and TB number. Patients with CD3<sup>+</sup> T-cell 36 density in WTS and mean CD3<sup>+</sup>CD8<sup>+</sup> T-cell number within 0–50 µm of TBs below the cutoff 37 point and TB number above the cutoff point were classified as a "high risk" of disease 38 specific death group; the remainder of the patients were classified as a "low-risk" group. KM 39 curves and bootstrap univariate cox regression p values were used to determine the 40 significance of this index. The created TBISI was highly significant in the prediction of 41 disease specific death from both KM analysis and cox regression (HR = 18.75, 95%CI 6.46-42 54.43;  $p = 1.202 \times 10^{-13}$ ) (Fig. 3J). KM and univariate cox-regression analyses were also 43 applied to pT stage (HR = 4.143, 95% CI 1.48-11.57; P = 0.0033) (Fig. 3A), TB number (HR 44

1 = 5.899, 95% CI 1.875–18.55; P = 0.0006) (Fig. 3D) and the studies' calculated 2 Immunoscore (HR = 7.02, 95% CI 2.49–19.84;  $P = 1.922 \times 10^{-05}$ ) (Fig. 3G). Multivariate 3 Cox regression model (forward stepwise) revealed that this TBISI was the only feature that 4 added value to the model when pT stage, TB number, Immunoscore, and TBISI were 5 included (Supplementary Table S4). Finally, the ROC curve showed that the TBISI had the 6 greatest area under the curve (Area = 0.785, 95% CI 0.629–0.941) when compared to pT 7 stage or each of the model's component individually (Supplementary Fig. S2).

#### 8 Validation of Tumor Budding, Immunoscore and Tumor Bud-Immuno Spatial Index

9 The TBISI developed from the training set, alongside the Immunoscore and TBs, were 10 evaluated on two independent validation cohorts; Validation Cohort 1 patients from Edinburgh hospitals (n = 56) and International Validation Cohort 2 patients from the 11 12 NDMCH, Japan (n = 62). Cutoff points calculated from the training set data were directly 13 applied to the two validation cohorts. Univariate Cox regression and KM analyses were 14 calculated using the patient data from the two validation cohorts and used to assess the clinicopathological data, TB number, immunoscore, and the model TBISI (Table 1). pT stage 15 was significantly associated with patient survival in validation cohort 1 (HR = 5.00, 95% CI 16 1.52–16.46; P = 0.008) (Fig. 3B), but not in the Japanese validation cohort 2 (Fig. 3C). TB 17 number was significant in both validation cohort 1 and 2 (HR = 5.29, 95% CI 1.14–24.50; P 18 = 0.033 and HR = 8.816, 95% CI 2.70–28.82; P = 0.0003) (Fig. 3E and 3F respectively), 19 whereas the immunoscore was only significant in the validation cohort 1 (HR = 4.72, 95% CI 20 1.02–21.87; P = 0.047) (Fig. 3H), although trended to significance in validation cohort 2 21 (Fig. 3I). 22

TBISI was highly significant on both validation cohorts; Validation Cohort 1 with HR = 12.27, 95% CI 3.52–42.73;  $p = 8.2 \times 10^{-05}$  and in Validation Cohort 2 with HR = 15.61, 95% CI 4.69–51.91;  $p = 7.42 \times 10^{-06}$  (Fig. 3K and 3L, respectively). The TBISI demonstrated an increase in hazard ratio and significance in both validation cohorts than when analyzing the sum of its parts independently.

28

#### 1 **Discussion**

2 Risk assessment and thus treatment choices for stage II CRC patients are in need of improvement. A growing awareness exists that the TME contributes to cancer differentiation, 3 progression, invasion, and metastasis (27-29). In CRC, the two most promising candidate 4 prognostic features involve two distinct aspects of the TME: tumor budding (2,30-32) and 5 the Immunoscore (9,10,14,33). Tumor budding represents small clusters of infiltrating cancer 6 cells within the IM, whereas the Immunoscore quantifies tumor infiltrating lymphocytes 7 (TILs) within both the IM and the CT. However, these features are predominantly assessed 8 independently of each other. The question, therefore, arises as to whether these two features 9 combined augment their individual prognostic significance and whether their association and 10 spatial relationship adds further prognostic value for stage II CRC patients. The work 11 presented here utilizes automated image analysis to quantify and compare TBs and TILs 12 coregistered to the same tissue section. 13

We report four major findings: first, we have shown significant associations between clinicopathological factors, CD3<sup>+</sup> CD8<sup>+</sup> T-cell densities, and TB number; second, we have confirmed that Immunoscore and tumor budding are strong independent prognostic factors for disease specific survival in stage II CRC; third, we have demonstrated that the spatial interaction between lymphocytes and TBs holds additional prognostic significance; and finally, a standardized prognostic index was created combining all the above features to achieve a higher significant cohort stratification than any individual prognostic feature tested.

Emerging technologies in tissue analysis have allowed further understanding of the role of 21 the TME in disease progression. Automated image analysis has been shown to have a high 22 potential for unbiased and reproducible assessment of histopathological features in CRC, 23 such as for TBs, lymphatic vessel invasion (12), and TILs (14), as well as in other disease 24 types (34,35). To an extent, this is assisted by the advancement of acquiring multiparametric 25 data from a single tissue section, which can provide a more complete understanding of the 26 underlying mechanisms within TME. though 27 the Even some multiplex immunohistochemistry or immunofluorescence methodologies have shown the ability of 28 29 high-level multiplexing on a single FFPE tissue sample, the analysis may be restricted to manually selected regions of interest or through their applications on tissue microarrays (36). 30 Such methodologies can also be associated with long acquisition times for whole tissue 31 sections and sequential stitching of image tiles into one large image (37). In this study we 32 quantified TILs and TBs coregistered to a single whole slide section through the use of four-33 plexed immunofluorescence, whole slide scanning, and automated image analysis. This 34 methodology permitted the colocalization of the four tissue markers, required to quantify the 35 features measured in this study, across the whole tissue section and at single cell resolution. 36 Spatial coordinates of each cell type were exported from the same tissue section ensuring 37 more accurate analysis than is achieved from coregistering serial sections. This methodology 38 39 therefore conserves precious tissue, reduces scanning time and cost, while also allowing the 40 objective analysis of the entire TME and its cellular interactions.

Our results showed that the presence of high CD3<sup>+</sup> T-cell density correlated with favorable clinicopathological features, at the IM with the absence of EMLVI and at the CT with moderate differentiation status and non-mucinous histological type. These data concur well with prognostic analyses on the propitious impact of overall TIL densities in CRC patients (10,38). We also found that a high CD8 T-cell density was correlated with the female gender, a finding that has previously been shown in invasive CRC by Jang (39). However, the mechanisms underlying this observation remain unknown. An elevated number of TBs was significantly associated with advanced pT stage, correlating favorably with previous literature showing TBs being associated with adverse prognostic features (40–42). These findings highlight the impairing effect T cells have on tumor progression, while suggesting that high tumor budding cancers harbor a more aggressive phenotype.

8 Our data indicate a significant inverse relationship between the densities of TILs and TB number, which substantiates the work of Zlobec et al. (43), who found the absence of TILs to 9 be associated with presence of tumor budding. This may suggest that during the transition of 10 TBs from epithelial to mesenchymal phenotype, they might occupy a niche that may not 11 illicit an immune response. Indeed, it has been suggested that TBs lose MHC expression 12 during this transition (7), and others have shown that TB positivity is significantly associated 13 with PD-L1 positivity (44). The data presented here adds further support to the concept of 14 TBs having the ability to evade the antitumoral host response and thereby embark on the first 15 steps of the metastatic cascade. 16

Despite repeated evidence of tumor budding conferring prognostic significance in CRC 17 (8,12,42,45), its routine clinical assessment has not yet been established due to the lack of 18 standardized methodology of assessment. Most studies investigating tumor budding rely upon 19 the use of manual quantification, often based on subjective selection of high magnification 20 regions of interest (2). The use of cytokeratin immunohistochemistry has previously shown to 21 improve the detection of TBs as well as increasing inter-observer reproducibility (30). 22 Furthermore, cytokeratin immunohistochemistry has been recommended by the International 23 Tumor Bud Consensus Conference to help TB quantification in challenging cases such as 24 tumors regions with strong inflammation or ruptured glands (2). In the current study, tumor 25 budding was identified by the use of cytokeratin immunofluorescence and quantified by 26 automated and standardized image analysis across the entire TBROI. Previous studies have 27 28 highlighted the difficulty in the qualitative assessment of TBs in circumstances of gland fragmentation, stromal cells mimicking TBs, inflammation (46), microvesicles, and 29 membrane fragments that might be cytokeratin-positive (30). In order to address these 30 concerns, we ensured the presence of whole nuclei (n = 1-4) for the TB identification and 31 only counted the isolated clusters of cells as buds. Quantifying TBs at the whole TBROI has 32 the advantage of being representative of the whole invasive margin rather than a manually 33 selected region of interest. However, our methodology has the potential to "dilute" the 34 significance of TBs represented by hotspots due to the tumor's innate heterogeneity. Like 35 previous semi-quantitative studies (6,42) our quantification methodology reported TB 36 number and density at the TBROI to be significantly correlated to poor patient survival. 37

The Immunoscore, proposed by Galon et al. (38,47,48), has been validated in a large international colon cancer study (14). It is not only a promising prognostic index (11,38), but it has been shown to be superior to TNM staging when assessing CRC prognosis (47,49). This score is based on the quantification of the *in situ* immune infiltration by the chromogenic labelling of two sequential tissue sections; one with CD3<sup>+</sup> T cells and one with CD8<sup>+</sup> T cells and quantified in two regions (IM and CT). By applying our automated image analysis workflow across a single tissue section, our Immunoscore results compared favorably with those of Galon et al. (9), showing that a high density of TILs was correlated
with better survival outcomes in stage II CRC.

3 In order to reflect the dynamic processes present at the tumor front, T lymphocytes in close (50 and 100 µm) proximity of TBs in a 2-dimensional plot were quantified. Our results 4 5 revealed that a high number of T lymphocytes near TBs was associated with better survival. This supports the theory that TBs represent a heterogeneous subpopulation of cells and, 6 although hypothesized to be more invasive than well differentiated tumor glands, retain the 7 potential to be recognized by immune-surveillance mechanisms. This process has previously 8 been described as "nipping in the bud" (43). This theory was also supported by a study on the 9 microenvironment of TBs by Lugli et al. (50), reporting high lymphocyte to TB ratio as a 10 good prognostic factor in patients with CRC and by Lang-Schwarz et al. (51), reporting the 11 combination of both TILs and tumor budding predicting survival in CRC. Due to the high 12 complexity and heterogeneity within the whole tissue slide, spatial mapping of specific 13 features by eye is difficult, subjective, and time consuming. Selected regions of interest to 14 study this interplay between different features and cells might not represent the spatial 15 relationships present in the whole tissue. Here we propose a rapid and completely unbiased 16 method capturing every single event at the single cell resolution and therefore better reporting 17 on the interactions among TBs and TILs seen at the whole IM. Furthermore, such 18 methodology can reveal specific patterns that may advance our understanding of the 19 interactions occurring between cancer cells and their microenvironment. 20

Multiple features reported from the clinicopathological report and by automated image 21 analysis demonstrated prognostic significance. In order to reduce the dimensionality of the 22 data and identify the independently significant features, a Cox regression model with LASSO 23 regularization was applied to all 32 reported features in this study. This reported a reduced 24 and independently significant set of 8 features: 4 from the clinicopathological report and 4 25 from image analysis. This reduced feature set was input for a RF machine learning model, 26 which consisted of 500 trees. The advantage of feature selection through RF is the thorough 27 28 testing of all significant features across multiple models while building in validation. This machine learning application reported only 4 features with a high mean decrease Gini 29 coefficient, all of which were exported from image analysis. In order to avoid overfitting of 30 our model on the training cohort, we included multiple validation steps within the workflow. 31 Through this, we demonstrate that a model in which patients with a combined low CD3<sup>+</sup> T-32 cell density in WTS, low mean number of TILs within 50 µm proximity to TBs, and high TB 33 number conferred a survival disadvantage compared to any other combination. When a 34 multivariate forward stepwise Cox regression including pT stage, TB number, Immunoscore, 35 and TBISI was applied, the only feature reported to significantly add value to the model was 36 the TBISI, whereas pT stage, TB number, and Immunoscore were not included in the 37 equation. The new prognostic model of TBISI was then successfully validated across two 38 independent cohorts, the second of which included patients with different genetic 39 background, tumor genetic features, and gut microbiota, compared with the first cohort. This 40 model and its cutpoints did not need to be altered for the Japanese validation cohort despite 41 the fact that their tissue was sectioned longitudinally compared to the other cohorts that were 42 cut at a cross-section. pT stage in the Japanese cohort, unlike both Edinburgh ones, was not 43 significantly correlated with DSS in univariate analysis. This reflects the heterogeneous 44 45 nature of stage II CRC disease and further highlights the need for additional methodologies,

1 such as the TBISI reported here, to more accurately stratify these patients for both prognostic

2 reasons and potentially identifying patients that may benefit from adjuvant therapy.

3 In conclusion, this study reports an automated image analysis-based workflow with the ability to quantify the tumor-infiltrating immune cells; total T cells (CD3<sup>+</sup>) and cytotoxic T 4 5 cells (CD8<sup>+</sup>), and TBs at the invasive front, across a single tissue section. Additionally, through a machine learning approach, our results show evidence that the spatial association of 6 lymphocytes and TBs has a high prognostic significance in stage II CRC patients. This 7 combinational prognostic model demonstrated augmented accuracy and precision over that 8 gained by either characterizing the lymphocytic infiltration or tumor budding in isolation. 9 Furthermore, the final model contained no clinical parameters, thus demonstrating the benefit 10 of automated profiling of the TME to provide a more precise and accurate prognosis. The 11 methodology completely removes human subjectivity and negates the need for experienced 12 staff to spend valuable time quantifying complex features across large areas of a whole slide 13 section. This research can serve as a base for future studies on the prognostic significance of 14 the interplay between different cell types within the patient's heterogeneous and heterotypic 15 16 TME.

**Table 2. Lymphocyte distribution patterns and tumor bud number in relation to clinicopathological characteristics.** IM = invasive margin, CT = tumor core, WTS = whole tumor section, TB = tumor bud, Max.Tum.Diam = Maximum Tumor Diameter, Ap.Node.Exam = Apical Node Exam, EMLVI = Extramural lymphovascular invasion. \* Statistical significance, Chi-Square.

Factures	Coefficients					
Features —	LASSO	Mean Decrease Gini				
CD3 <sup>+</sup> density in WTS	-0.0006	5.7932				
Mean CD3 <sup>+</sup> CD8 <sup>+</sup> number within 0-50µm of TB	-0.8951	5.4673				
TB Number	0.0004	4.7092				
CD8 <sup>+</sup> density in CT	-0.0004	4.4586				
рТ	0.8394	1.3724				
EMLVI	-0.8623	1.1499				
Age	0.5791	1.1071				
Differentiation	0.4967	0.9728				

**Table 3. LASSO penalized Cox proportional hazard regression and Random Forest Gini coefficients for the significant features.** WTS = whole tumor section, CT = tumor core, TB = tumor bud, EMLVI = Extramural lymphovascular invasion.

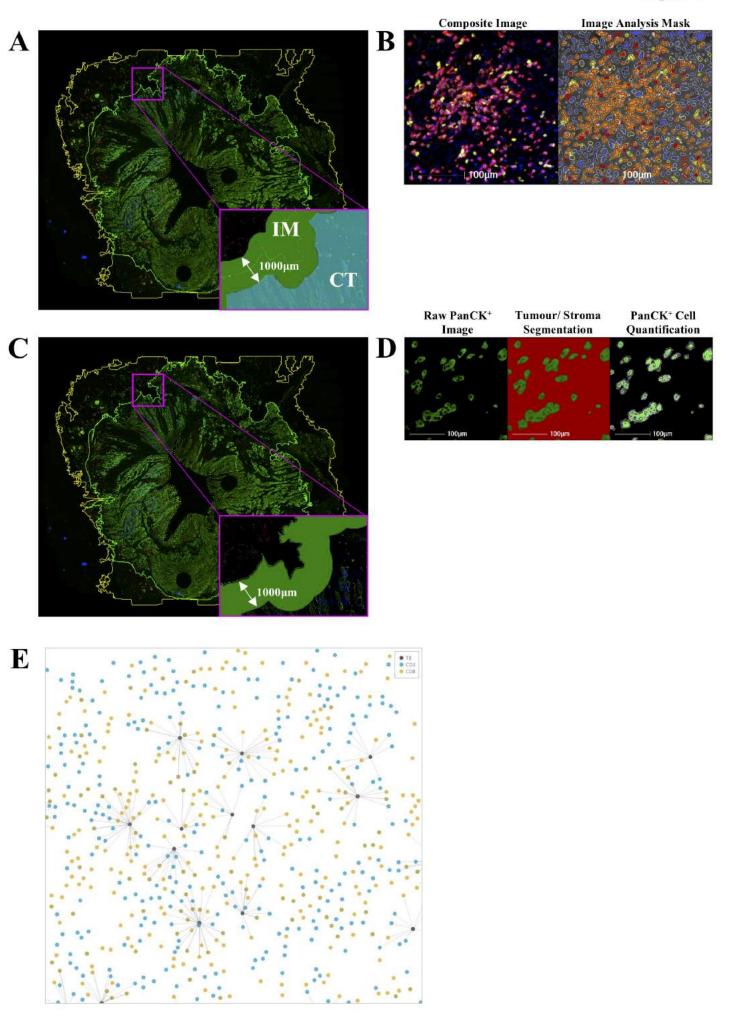

#### **Figure Legends:**

**Figure 1. Digital image analysis method. A)** Full tissue area (yellow line) and invasive front (green line) are outlined, pancytokeratin (PanCK),  $CD3^+$ , and  $CD8^+$  cells annotated in green, yellow and red respectively; invasive margin region is highlighted in green (IM) and the tumor core region in blue (CT), **B**) detection and classification of lymphocyte cell type (CD3<sup>+</sup> cells in yellow,  $CD8^+$  cells in red and their colocalization in orange mask), **C**) Full tissue area (yellow line) and Invasive front (green line) are outlined, PanCK,  $CD3^+$ , and  $CD8^+$  cells annotated in green, yellow, and red, respectively; area of tumor bud quantification is highlighted in green, **D**) tumor to stroma segmentation and PanCK cell quantification within the tumor areas, **E**) Proximity Analysis of lymphocytes to tumor buds (TBs).  $CD3^+$  cells are shown in blue,  $CD8^+$  cells in orange, and TBs in gray. Proximity line series is shown for lymphocytes within 50 µm of TBs.

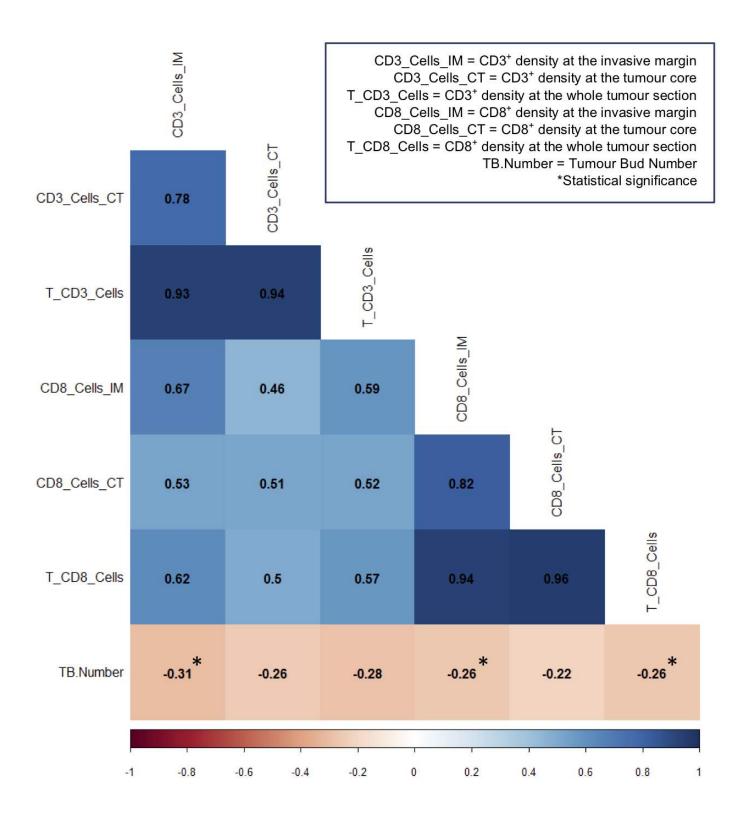

**Figure 2. Spearman correlation matrix for lymphocyte densities and tumor bud number.** Spearman correlation coefficient is shown for all relationships. A coefficient with either +1 (blue), 0 (white), or -1 (red) value indicates a perfect association, no association, and a perfect negative association of ranks, respectively.

Figure 3. Kaplan Meier survival analysis for pT stage, tumor bud (TB) number, immunoscore, and Tumor Bud-Immuno spatial index (TBISI) for training cohort, validation cohort 1, and validation cohort 2. (A) pT stage for training cohort, (B) pT stage for validation cohort 1, and (C) pT stage for validation cohort 2. (D) TB number for training cohort, (E) TB number for validation cohort 1, and (F) TB number for validation cohort 2; High represents the group of patients with TB number above the optimal cutoff point (1104.0). Low represents the group of patients with TB Number below the cutoff point. (G) Immunoscore for training cohort, (H) Immunoscore for validation cohort 1, and (I) Immunoscore for validation cohort 2. High Immunoscore represents the group of patients with an Immunoscore > 2, and Low Immunoscore represents the group of patients with an Immunoscore  $\leq 2$ . (J) TBISI for training cohort, (K) TBISI for validation cohort 1, and (L) TBISI for validation cohort 2. High risk represents the group of patients who have CD3<sup>+</sup> density in whole tumor section and mean CD3<sup>+</sup>CD8<sup>+</sup> cell number within 0–50 µm of TBs below the cutoff point (389.6 cells / mm<sup>2</sup> and 4.1, respectively) and TB number above the cutoff point (1104.0). Low risk represents all other patients.
