ABSTRACT

Based on HARPS-N radial velocities (RVs) and *TESS* photometry, we present a full characterisation of the planetary system orbiting the late G dwarf TOI-561. After the identification of three transiting candidates by *TESS*, we discovered two additional external planets from RV analysis. RVs cannot confirm the outer *TESS* transiting candidate, which would also make the system dynamically unstable. We demonstrate that the two transits initially associated with this candidate are instead due to single transits of the two planets discovered using RVs. The four planets orbiting TOI-561 include an ultra-short period (USP) super-Earth (TOI-561 b) with period $P_b = 0.45$ d, mass $M_b = 1.59 \pm 0.36 M_\oplus$ and radius $R_b = 1.42 \pm 0.07 R_\oplus$, and three mini-Neptunes: TOI-561 c, with $P_c = 10.78$ d, $M_c = 5.40 \pm 0.98 M_\oplus$, $R_c = 2.88 \pm 0.09 R_\oplus$; TOI-561 d, with $P_d = 25.6$ d, $M_d = 11.9 \pm 1.3 M_\oplus$, $R_d = 2.53 \pm 0.13 R_\oplus$; and TOI-561 e, with $P_e = 77.2$ d, $M_e = 16.0 \pm 2.3 M_\oplus$, $R_e = 2.67 \pm 0.11 R_\oplus$. Having a density of $3.0 \pm 0.8 \text{ g cm}^{-3}$, TOI-561 b is the lowest density USP planet known to date. Our N-body simulations confirm the stability of the system and predict a strong, anti-correlated, long-term transit time variation signal between planets d and e. The unusual density of the inner super-Earth and the dynamical interactions between the outer planets make TOI-561 an interesting follow-up target.

Key words: planets and satellites: detection – planets and satellites: composition – star: individual: TOI-561 (TIC 377064495, *Gaia* DR2 3850421005290172416) – techniques: photometric – techniques: radial velocities

1 INTRODUCTION

The *Transiting Exoplanet Survey Satellite* (*TESS*, Ricker et al. 2014) is a NASA all-sky survey designed to search for transiting planets around bright and nearby stars, and particularly targeting stars that could reveal planets with radii smaller than Neptune. Since the beginning of its observations in 2018, *TESS* has discovered more

than 66 exoplanets, including about a dozen multi-planet systems (e.g. Dragomir et al. 2019; Dumusque et al. 2019; Günther et al. 2019). Multi-planet systems, orbiting the same star and having formed from the same protoplanetary disc, offer a unique opportunity for comparative planetology. They allow for investigations of the formation and evolution processes, i.e. through studies of relative planet sizes and orbital separations, orbital inclinations relative to the star’s rotation axis, mutual inclination of the orbits, etc. In order to obtain a complete characterisation of a

* E-mail: gaia.lacedelli@phd.unipd.it

system, knowledge of the orbital architecture and the bulk composition of the planets are essential. To obtain such information, transit photometry needs to be combined with additional techniques that allow for the determination of the planetary masses, i.e. radial velocity (RV) follow-up or transit time variation (TTV) analysis. Up to now, the large majority of known planetary systems have been discovered by the *Kepler* space telescope (Borucki et al. 2010), which has led to an unprecedented knowledge of the ensemble properties of multiple systems (e.g. Latham et al. 2011; Millholland et al. 2017; Weiss et al. 2018), their occurrence rate (e.g. Fressin et al. 2013), and their dynamical configurations (e.g. Lissauer et al. 2011; Fabrycky et al. 2014). However, many of the *Kepler* targets are too faint for RV follow-up, so most of the planets do not have a mass measurement, preventing a comprehensive understanding of their properties, and of the planetary system. Thanks to the *TESS* satellite, which targets brighter stars, an increasing number of candidates suitable for spectroscopic follow-up campaigns are being discovered. These new objects will increase the number of well characterised systems, and will provide a valuable observational counterpart to the theoretical studies on the formation and evolution processes of planetary systems (e.g. Morbidelli et al. 2012; Raymond et al. 2014; Helled et al. 2014; Baruteau et al. 2014, 2016; Davies et al. 2014).

In this paper, we combine *TESS* photometry (Section 2.1) and high precision RVs gathered with the HARPS-N spectrograph (Section 2.2) to characterise the multi-planet system orbiting the star TOI-561. The *TESS* pipeline identified three candidate planetary signals, namely an ultra-short period (USP) candidate ($P \sim 0.45$ days), and two additional candidates with periods of ~ 10.8 and ~ 16.4 days. We determined the stellar properties (Section 3) using three independent methods. Based on our activity analysis, we concluded that TOI-561 is an old, quiet star, and therefore quite appropriate for the study of a complex planetary system. After assessing the planetary nature of the transit-like features (Section 4), we performed a series of analysis – with the tools described in Section 5 – to determine the actual system configuration (Section 6). We further address the robustness of our final solution based on a comparison with other possible models (Section 7). We finally compare the resulting planetary densities with the distribution of known planets in the mass-radius diagram and we predict the expected TTV signal for the planets in the system (Section 8).

2 OBSERVATIONS

2.1 *TESS* photometry

TOI-561 was observed by *TESS* in two-minute cadence mode during observations of sector 8, between 2 February and 27 February 2019. The astrometric and photometric parameters of the star are listed in Table 1. Considering the download time, and the loss of 3.26 days of data due to an interruption in communications between the instrument and the

spacecraft that occurred during sector 8¹, a total of 20.22 days of science data were collected. The photometric observations for TOI-561 were reduced by the Science Processing Operations Center (SPOC) pipeline (Jenkins et al. 2016; Jenkins 2020), which detected three candidate planetary signals, with periods of 10.8 days (TOI-561.01), 0.4 days (TOI-561.02), and 16.4 days (TOI-561.03), respectively. The pipeline identified 55 transits of TOI-561.02, two transits of TOI-561.01, and two transits of TOI-561.03, with depths of 290, 1207, and 923 ppm and signal-to-noise-ratios (S/N) of 10.0, 9.8 and 9.2, respectively. For our photometric analysis, we used the light curve based on the Pre-search Data Conditioning Simple Aperture Photometry (PDCSAP, Smith et al. 2012; Stumpe et al. 2012, 2014). We downloaded the two-minute cadence PDCSAP light curve from the Mikulski Archive for Space Telescopes (MAST)², and removed all the observations encoded as *NaN* or flagged as bad-quality (*DQUALITY*>0) points by the SPOC pipeline³. We performed outliers rejection by doing a cut at 3σ for positive outliers and 5σ (i. e. larger than the deepest transit) for negative outliers. We removed the low frequency trends in the light curve using the biweight time-windowed slider implemented in the *wotan* package (Hippke et al. 2019), with a window of 1.5 days, and masking the in-transit points to avoid modifications of the transit shape. In order to obtain an independent confirmation of the signals detected in the *TESS* light curve, we performed an iterative transit search on the detrended light curve using the Transit Least Squares (TLS) algorithm (Hippke & Heller 2019). The first three significant identified signals nicely matched the *TESS* suggested periods ($P_{\text{TLS}} = 10.78$ d, 0.44 d, 16.28 d).

In addition, we also extracted the 30-minutes cadence light curve from the *TESS* Full-Frame Images (FFIs) using the *PATHOS* pipeline (Nardiello et al. 2019), in order to obtain an independent confirmation of the detected signals (Section 4).

2.2 HARPS-N spectroscopy

We collected 82⁴ spectra using HARPS-N at the Telescopio Nazionale Galileo (TNG), in La Palma (Cosentino et al. 2012, 2014), with the goal of precisely determining the masses of the three candidate planets and to search for additional planets. The observations started on November 17, 2019 and ended on June 13, 2020, with an interruption between the end of March and the end of April due to the shut down of the TNG because of Covid-19. In order to precisely characterise the signal of the USP candidate, we collected 6 points per night on February 4 and February 6, 2020, thus covering the whole phase curve of the planet, and two points per night (when weather allowed) during the period of maximum visibility of the target (February-March 2020). The

exposure time was set to 1800 seconds, which resulted in a S/N at 550 nm of 77 ± 20 (median ± standard deviation) and a measurement uncertainty of 1.2 ± 0.6 m s⁻¹. We reduced the data using the standard HARPS-N Data Reduction Software (DRS) using a G2 flux template (the closest match to the spectral type of our target) to correct for variations in the flux distribution as a function of the wavelength, and a G2 binary mask to compute the cross-correlation function (CCF, Baranne et al. 1996; Pepe et al. 2002). All the observations were gathered with the second fibre of HARPS-N illuminated by the Fabry-Perot calibration lamp to correct for the instrumental RV drift, except for the night of May 31, 2020. This observation setting prevented us from using the second fibre to correct for Moon contamination. However, we note that the difference between the systemic velocity of the star and the Moon is always greater than 15 km s⁻¹, therefore preventing any contamination of the stellar CCF (as empirically found by Malavolta et al. 2017a and subsequently demonstrated through simulations by Roy et al. 2020), as the average full width at half maximum (FWHM) of the CCF for TOI-561 is 6.380 ± 0.004 km s⁻¹.

The RV data with their 1 σ uncertainties and the associated activity indices (see Section 3.3 for more details) are listed in Table 2. Before proceeding with the analysis, we removed from the total dataset 5 RV measurements, with associated errors greater than 2.5 m s⁻¹ from spectra with S/N < 35, that may affect the accuracy of our results. The detailed

procedure performed to identify these points is described in Appendix B1.

3 STELLAR PARAMETERS

3.1 Photospheric parameters

We derived the photospheric stellar parameters using three different techniques: the curve-of-growth approach, spectral synthesis match, and empirical calibration.

The first method minimizes the trend of iron abundances (obtained from the equivalent width, EW, of each line) with respect to excitation potential and reduced EW respectively, to obtain the effective temperature and the microturbulent velocity, ξ_t . The gravity $\log g$ is obtained by imposing the same average abundance from neutral and ionised iron lines. We obtained the EW measurements using ARESv2⁵ (Sousa et al. 2015). We used the local thermodynamic equilibrium (LTE) code MOOG⁶ (Snedden 1973) for the line analysis, together with the ATLAS9 grid of stellar model atmosphere from Castelli & Kurucz (2003). The whole procedure is described in more detail in Sousa (2014). We performed the analysis on a co-added spectrum (S/N > 600), and after applying the gravity correction from Mortier et al. (2014) and adding systematic errors in quadrature (Sousa et al. 2011), we obtained $T_{\text{eff}} = 5346 \pm 69$ K, $\log g = 4.60 \pm 0.12$, $[\text{Fe}/\text{H}] = -0.40 \pm 0.05$ and $\xi_t = 0.78 \pm 0.08$ km s⁻¹.

The spectral synthesis match was performed using the Stellar Parameters Classification tool (SPC, Buchhave et al. 2012, 2014). It determines effective temperature, surface gravity, metallicity and line broadening by performing a cross-correlation of the observed spectra with a library of synthetic spectra, and interpolating the correlation peaks to determine the best-matching parameters. For technical reasons, we ran the SPC on the 62 GTO spectra only⁷: the S/N is so high that the spectra are anyway dominated by systematic errors, and including the A40TAC_23 spectra would not change the results. We averaged the values measured for each exposure, and we obtained $T_{\text{eff}} = 5389 \pm 50$ K, $\log g = 4.49 \pm 0.10$, $[\text{M}/\text{H}] = -0.36 \pm 0.08$ and $v \sin i < 2$ km s⁻¹. We finally used CCFpams⁸, a method based on the empirical calibration of temperature, metallicity and gravity on several CCFs obtained with subsets of stellar lines with different sensitivity to temperature (Malavolta et al. 2017b). We obtained $T_{\text{eff}} = 5293 \pm 70$ K, $\log g = 4.50 \pm 0.15$ and $[\text{Fe}/\text{H}] = -0.40 \pm 0.05$, after applying the same gravity and systematic corrections as for the EW analysis.

We list the final spectroscopic adopted values, i.e., the weighted averages of the three methods, in Table 3.

From the co-added HARPS-N spectrum, we also derived the chemical abundances for several refractory elements (Na, Mg, Si, Ca, Ti, Cr, Ni). We used the ARES+MOOG method assuming LTE, as described earlier. The reference for solar

values was taken from [Asplund et al. \(2009\)](#), and all values in Table 3 are given relative to the Sun. Details on the method and line lists are described in [Adibekyan et al. \(2012\)](#) and [Mortier et al. \(2013\)](#). This analysis shows that this iron-poor star is alpha-enhanced. Using the average abundances of magnesium, silicon, and titanium to represent the alpha-elements and the iron abundance from the ARES+MOOG method (for consistency), we find that $[\alpha/Fe] = 0.23$.

3.2 Mass, radius, and density of the star

For each set of photospheric parameters, we determined the stellar mass and radius using *isochrones* ([Morton 2015](#)), with posterior sampling performed by *MultiNest* ([Feroz & Hobson 2008](#); [Feroz et al. 2009, 2019](#)). We provided as input the parallax of the target from the *Gaia* DR2 catalogue, after adding an offset of $+50 \pm 7 \mu\text{as}$ (with the error added in quadrature to the parallax error) as suggested by [Khan et al. \(2019\)](#), plus the photometry from the TICv8, 2MASS and *WISE* (Table 1). We used two evolutionary models, the MESA Isochrones & Stellar Tracks (MIST, [Dotter 2016](#); [Choi et al. 2016](#); [Paxton et al. 2011](#)) and the Dartmouth Stellar Evolution Database ([Dotter et al. 2008](#)). For all methods, we assumed $\sigma_{T_{\text{eff}}} = 70 \text{ K}$, $\sigma_{\log g} = 0.12$, $\sigma_{[\text{Fe}/\text{H}]} = 0.05$ (except for SPC, where we kept the original error of 0.08) as a good estimate of the systematic errors regardless of the internal error estimates, to avoid favouring one technique over the others when deriving the stellar mass and radius. We also imposed an upper limit on the age of 13.8 Gyr, i.e. the age of the Universe ([Planck Collaboration et al. 2018](#)). From the mean and standard deviation of all the posterior samplings we obtained $M_{\star} = 0.785 \pm 0.018 M_{\odot}$ and $R_{\star} = 0.849 \pm 0.007 R_{\odot}$. We derived the stellar density $\rho_{\star} = 1.285 \pm 0.040 \rho_{\odot}$ ($\rho_{\star} = 1.809 \pm 0.056 \text{ g cm}^{-3}$) directly from the posterior distributions of M_{\star} and R_{\star} .

We summarise the derived astrophysical parameters of the star in Table 3, which also reports temperature, gravity and metallicity obtained from the posteriors distributions resulting from the *isochrone* fit. A lower limit on the age of ~ 10 Gyr is obtained considering the 15.86-th percentile of the distribution of the combined posteriors, as for the other parameters. We note however that an isochrone fit performed through EXOFASTv2 ([Eastman et al. 2019](#)), assuming the photometric parameters in Table 1 and the spectroscopic parameters in Table 3, using only the MIST evolutionary set, returned a lower limit on the age of 5 Gyr, while all the other parameters were consistent with the results quoted in Table 3. Thus, we decided to assume 5 Gyr as a conservative

lower limit for the age of the system. The old stellar age and the sub-solar metallicity suggest that TOI-561 may belong to an old Galactic population, an hypothesis that is also supported by our kinematic analysis. In fact, we derived the Galactic space velocities using the astrometric properties reported in Table 1. For the calculations we used the *astropy* package, and we assumed the *Gaia* DR2 radial velocity value of 79.54 km s^{-1} , obtaining the heliocentric velocity components $(U, V, W) = (-60.0, -70.8, 16.7) \text{ km s}^{-1}$, in the directions of the Galactic center, Galactic rotation, and north Galactic pole, respectively. The derived *UVW* velocities point toward a thick-disk star, as confirmed by the probability membership derived following [Bensby et al. \(2014\)](#), that implies a $\sim 70\%$ probability that the star belongs to the thick disc, a $\sim 29\%$ probability of being a thin-disc star and a $\sim 0.0004\%$ probability of belonging to the halo.

3.3 Stellar activity

The low value of the $\log R'_{\text{HK}}$ index (-5.003 ± 0.012), derived using the calibration by Lovis et al. (2011) and assuming $B - V = 0.71$, indicates that TOI-561 is a relatively quiet star. Given its distance of ≈ 86 pc, the lack of interstellar absorption near the Na D doublet in the HARPS-N co-added spectrum, and the total extinction in the V band from the isochrone fit (0.1 mag), we do not expect any significant effect of the interstellar medium on the $\log R'_{\text{HK}}$ index (Fossati et al. 2017). Nevertheless, it is important to check whether the star is showing any sign of activity in all the activity diagnostics at our disposal. In addition to the $\log R'_{\text{HK}}$ index, FWHM, and bisector span (BIS) computed by the HARPS-N DRS, we included in our analysis the V_{asy} (Figueira et al. 2013) and ΔV (Nardetto et al. 2006) asymmetry indicators, as implemented by Lanza et al. (2018), and the chromospheric activity indicator $H\alpha$ (Gomes da Silva et al. 2011).

The Generalized Lomb-Scargle (GLS, Zechmeister & Kürster 2009) periodograms of the above-mentioned indexes, computed within the frequency range $0.0005\text{--}0.5\text{ d}^{-1}$, i.e., 2–2000 days, are shown in Figure 1, together with the periodograms of the RVs and *TESS* photometry. For each periodogram, we also report the power threshold corresponding to a False Alarm Probability (FAP) of 1% and 0.1%, computed with a bootstrap approach. The periodogram of the RVs reveals the presence of significant peaks at ≈ 25 days, ≈ 180 days, ≈ 10 days (corresponding to one of the transiting planet candidates), and ≈ 78 days, ordered decreasingly according to their power. None of these peaks has a counterpart in the activity diagnostics here considered, as no signals with a FAP lower than 2.4% can be identified, strongly supporting that the signals in the RVs are not related to stellar activity. We note that the GLS periodogram of the *TESS* light curve identified a periodicity around 3.5 days with an amplitude of 0.13 ppt and a power of 0.014, that is, above the 0.1% FAP threshold. However, it is unlikely that such variability is associated with stellar activity, since a rotational period of just a few days would be extremely atypical for a star older than 1 Gyr (e.g. Douglas et al. 2019), and in contrast with the lack of any signal in all the other above-mentioned activity indicators. Indeed, the rotational period estimated from the $\log R'_{\text{HK}}$ using the calibrations of Noyes et al. (1984) and Mamajek & Hillenbrand (2008) supports this assertion, indicating a value around 33 d. We note that this value of the rotational period should be considered as a rough estimate, also because these calibrations are not well tested for old and alpha-enhanced stars like TOI-561. Further evidence against a ~ 3.5 d rotational period is provided by the low value of the $v \sin i$ ($< 2\text{ km s}^{-1}$), that suggests a rotational period > 21.5 d, assuming the stellar radius listed in Table 3 and an inclination of 90° . In any case, we verified with a periodogram analysis that our light curve flattening procedure correctly removed the here identified signal at 3.5 days.

In addition, we performed an auto correlation analysis, following the prescription by McQuillan et al. (2013), on the *TESS* light curve (with the transits filtered out), and the ASAS-SN V and g photometry (Shappee et al. 2014; Kochanek et al. 2017), after applying a $5\text{-}\sigma$ filtering, but no

significant periodicity could be identified. A periodogram analysis of the ASAS-SN light curves in each band, either by taking the full dataset or by analysing each observing season individually, confirmed these results.

In conclusion, if any activity is present, its signature must be below 0.8 ppt in the short period (rotationally-induced activity, < 30 days), and 20 ppt in the long term period (magnetic cycles, > 100 days), from the RMS of *TESS* and ASAS-SN photometry respectively. Incidentally, the former is close to the photometric variations of the Sun during the minimum at the end of Solar Cycle 25, when the Sun also reached a $\log R'_{\text{HK}}$ very close to the one measured for TOI-561 (Collier Cameron et al. 2019; Milbourne et al. 2019). By comparing our target to the Sun, and in general by taking into account the results of Isaacson & Fischer (2010), it is expected that the contribution to the RVs due to the magnetic activity of our star is likely below $1\text{--}2\text{ m s}^{-1}$. Since this value is quite close to the median internal error of our RVs, no hint of the rotational period is provided by either the photometry or the spectroscopic activity diagnostics, and the low activity level is consistent with our derived stellar age (> 5 Gyr), we do not include any activity contributions in the remaining of our analysis, except for an uncorrelated jitter term (σ_{jitter}).

4 RULING OUT FALSE POSITIVE SCENARIOS

Previous experience with *Kepler* shows that candidates in multiple systems have a much lower probability of being false positives (Latham et al. 2011; Lissauer et al. 2012). Nevertheless, it is always appropriate to perform a series of checks in order to exclude the possibility of a false positive.

We notice that the star has a good astrometric *Gaia* DR2 solution (Gaia Collaboration et al. 2018), with zero excess noise and a re-normalised unit weight error (RUWE) of 1.1, indicating that the single-star model provides a good fit to the astrometric observations. This likely excludes the presence of a massive companion that could contribute to the star's orbital motion in the *Gaia* DR2 astrometry, a fact that agrees with the absence of long-term trends in our RVs (see Section 6.1).

Moreover, the overall RV variation below 25 m s^{-1} and the shape of the CCFs of our HARPS-N spectra exclude the eclipsing binary scenario, which would be the most likely alternative explanation for the USP planet.

A further confirmation comes from the speckle imaging on the Southern Astrophysical Research (SOAR) telescope that Ziegler et al. (2020) performed on some of the *TESS* planet candidate hosts. According to their analysis (see Tables 3 and 6 therein), no companion is detected around TOI-561 (being the resolution limit for the star 0.041 arcsec, and the maximum detectable Δmag at separation of 1 arcsec 4.76 mag). Still, the 21 arcsec *TESS* pixels and the few-pixels wide point spread function (PSF) can cause the light from neighbours over an arc-minute away to contaminate the target light curve. In the case of neighbouring eclipsing binaries (EBs), eclipses can be diluted and mimic shallow planetary transits. For example, events at ~ 1 mmag level as in TOI-561.01 and TOI-561.03 can be mimicked by a nearby eclipsing binary within the *TESS* aperture with a 0.5% eclipse,

Figure 1. GLS periodogram of the RVs, the *TESS* photometry (PDCSAP) and the spectroscopic activity indexes under analysis. The main peak of each periodogram is highlighted with an orange vertical line. The grey vertical lines represent the signals corresponding to the transit-like signals with periods 10.8 and 16.3 days, and the additional signals identified in the RVs (Section 6) at ≈ 25 , ≈ 78 and ≈ 180 days. The dashed and dotted horizontal lines show the 1% and 0.1% FAP levels, respectively. The *TESS* periodogram shows a series of peaks below 10 days, unlikely to be associated with stellar activity given the old age of the star. The FWHM and the $\log R'_{\text{HK}}$ periodograms have the main peak at 244 and 220 days, respectively, so there is no correspondence with the 180 days signal. Moreover, both of them are below the 1% FAP. The bottom panel shows the window function of the data.

but no more than 7 magnitudes fainter. This condition is not satisfied in our case, as the only three sources within 100 arcsec from TOI-561 are all fainter than $T = 19.25$ mag and at a distance greater than 59 arcsec, according to the *Gaia* DR2 catalogue.

An independent confirmation was provided by the analysis of the in-/out-of-transit difference centroids on the *TESS* FFIs (Figure 2), adopting the procedure described in Nardiello et al. (2020). The analysis of the in-/out-of-transit stacked difference images confirms that, within a box of 10×10 pixels² ($\sim 200 \times 200$ arcsec²) centred on TOI-561, the transit events associated with candidates .01 and .03 occur on our target star, while candidate .02 has too few in-transit points in the 30-minute cadence images for this kind of analysis — in any case, its planetary nature will be confirmed by the RV signal of TOI-561 in Section 6.

Finally, in order to exclude the possibility that the transit-like features were caused by instrumental artefacts, we performed some additional checks on the light curve. We visually inspected the FFIs to spot possible causes (including instrumental effects) inducing transit-like features, and we could not find any. We re-extracted the short cadence light curve using the python package `lightkurve`⁹ (Lightkurve Collaboration et al. 2018) with different photometric masks and apertures, and we corrected them by using the *TESS* Cotrending Basis Vectors (CBVs); the final results were in agreement with the *TESS*-released PDCSAP light curve. We checked for systematics in every light curve pixel, and we found none. Ultimately, we checked for correlations between the flux, the local background, the (X,Y)-position from the PSF-fitting, and the FWHM, with no results. Therefore, we conclude that all the transit-like features in the light curve are real and likely due to planetary transits.

5 DATA ANALYSIS TOOLS

We performed the analysis presented in the next sections using PyORBIT¹⁰ (Malavolta et al. 2016, 2018), a convenient wrapper for the analysis of transit light curves and radial velocities.

In the analysis of the light curve, for each planet we fitted the central time of transit (T_0), period (P), planetary to stellar radius ratio (R_p/R_\star), and impact parameter b . In order to reduce computational time, we set a narrow, but still uninformative, uniform prior for period and time of transit, as defined by a visual inspection. We fitted a common value for the stellar density ρ_\star , imposing a Gaussian prior based on the value from Table 3. We included a quadratic limb-darkening law with Gaussian priors on the coefficients u_1 , u_2 , obtained through a bilinear interpolation of limb darkening profiles by Claret (2018)¹¹. We initially calculated the standard errors on u_1 , u_2 using a Monte Carlo approach that takes into account the errors on T_{eff} and $\log g$ as reported in Table 3, obtaining $u_1 = 0.393 \pm 0.007$ and

Figure 2. In-/out-of-transit difference centroid analysis of the transit events associated with the candidates TOI-561.01 (transit 2 and 3) and TOI-561.03 (transit 1 and 4). The star is centred at (0,0), and the grey circles are all the other stars in the *Gaia* DR2 catalogue, with dimension proportional to their apparent magnitude.

$u_2 = 0.204 \pm 0.001$. We however decided to conservatively increase the error on both coefficients to 0.05. In the fit we employed the parametrization (q_1 , q_2) introduced by Kipping (2013). Finally, we included a jitter term to take into account possible *TESS* systematics and short-term stellar activity noise. We assumed uniform, uninformative priors for all the other parameters, although the prior on the stellar density will inevitably affect the other orbital parameters. All the transit models were computed with the *batman* package (Kreidberg 2015), with an exposure time of 120 seconds and an oversampling factor of 10 (Kipping 2010).

In the analysis of the radial velocities, we allowed the periods to span between 2 and 200 days (i. e., the time span of our dataset) for the non-transiting planets, while we allowed the semi-amplitude K to vary between 0.01 and 100 m s^{-1} for all the candidate planets. These two parameters were explored in the logarithmic space. For the transiting candidates, we used the results from the photometric fit (see Appendix A) to impose Gaussian priors on period and time of transit on RV analysis alone, while using the same uninformative priors as for the photometric fit when including the photometric data as well.

For all the signals except the USP candidate, we assumed eccentric orbits with a half-Gaussian zero-mean prior on the eccentricity (with variance 0.098) according to Van Eylen et al. (2019), unless stated otherwise.

We computed the Bayesian evidence using the *MultiNest* nested-sampling algorithm (Feroz & Hobson 2008; Feroz et al. 2009, 2019) with the Python wrapper *pyMultiNest* (Buchner, J. et al. 2014). In the specific case of the joint light curve and RV analysis (Section 7), we employed the *dynesty* nested-sampling algorithm (Skilling 2004; Skilling 2006; Speagle 2020), which allowed for the

computation of the Bayesian evidence in a reasonable amount of time thanks to its easier implementation of the multi-processing mode. We performed a series of test on a reduced dataset, and we verified that the two algorithms provided consistent results with respect to each other. For all the analyses, we assumed 1000 live points and a sampling efficiency of 0.3, including a jitter term for each dataset considered in the model.

Global optimisation of the parameters was performed using the differential evolution code *PyDE*¹². The output parameters were used as a starting point for the Bayesian analysis performed with the *emcee* package (Foreman-Mackey et al. 2013), a Markov chain Monte Carlo (MCMC) algorithm with an affine invariant ensemble sampler (Goodman & Weare 2010). We ran the chains with $2n_{\text{dim}}$ walkers, where n_{dim} is the dimensionality of the model, for a number of steps adapted to each fit, checking the convergence with the Gelman-Rubin statistics (Gelman & Rubin 1992), with a threshold value of $\hat{R} = 1.01$. We also performed an auto-correlation analysis of the chains: if the chains were longer than 100 times the estimated auto-correlation time and this estimate changed by less than 1%, we considered the chains as converged. In each fit, we conservatively set the burn-in value as a number larger than the convergence point as just defined, and we applied a thinning factor of 100.

6 UNVEILING THE SYSTEM ARCHITECTURE

6.1 Planetary signals in the RV data

Before proceeding with a global analysis, we checked whether we could independently recover the signals identified by the *TESS* pipeline (Section 2.1) in our RV data only. The periodogram analysis of the RVs in Section 3.3 highlighted the presence of several peaks not related to the stellar activity. In particular, an iterative frequency search, performed subtracting at each step the frequency values previously identified, supplied the frequencies $f_1 = 0.039 \text{ d}^{-1}$ ($P_1 \approx 25.6 \text{ d}$), $f_2 = 0.006 \text{ d}^{-1}$ or 0.013 d^{-1} ($P_2 \approx 170 \text{ d}$ or $\approx 78 \text{ d}$) with the two frequencies being related to each other (i. e., removing one of them implies the vanishing of the other one), $f_3 = 0.093 \text{ d}^{-1}$ ($P_3 \approx 10.8 \text{ d}$, corresponding to the TOI-561.01 candidate), and $f_4 = 2.239 \text{ d}^{-1}$ ($P_4 \approx 0.45 \text{ d}$, corresponding to the TOI-561.02 candidate). After removing these four signals, no other clear dominant frequency emerged in the residuals. Since any attempt to perform a fit of the RVs to characterise the transiting candidates without accounting for additional dominant signals would lead to unreliable results, we decided to test the presence of additional planets in a Bayesian framework. We considered four models, the first one (Model 0) assuming the three transiting candidates only, i. e., TOI-561.01, .02, .03, and then including an additional planet in each of the successive models, i. e., TOI-561.01, .02, .03 plus one (Model 1), two (Model 2) and three (Model 3) additional signals, respectively. We computed the Bayesian evidence for each model using the

¹² <https://github.com/hpparvi/PyDE>

MultiNest nested-sampling algorithm, following the prescriptions as specified in Section 5. We report the obtained values in Table 4. According to this analysis, we concluded that the model with two additional signals, i.e., Model 2 (with no trend), is strongly favoured over the others, with a difference in the logarithmic Bayes factor $2\Delta\ln\mathcal{Z} > 10$ (Kass & Raftery 1995), both compared to the case with one or no additional signals. In the case of a third additional signal (Model 3), the difference with respect to the two-signal model was less than 2, indicating that there was no strong evidence to favour this more complex model over the simpler model with two additional signals only (Kass & Raftery 1995). We repeated the analysis first including a linear and then a quadratic trend in each of the four models. In all cases, the Bayesian evidence systematically disfavoured the presence of any trend¹³.

The first additional signal was associated with a candidate with $f \simeq 0.04 \text{ d}^{-1}$ ($P \simeq 25.6 \text{ d}$), which corresponds to the strongest peak in the RVs periodogram. Concerning the second additional signal, the **MultiNest** run highlighted the presence of two clusters of solutions, peaked at about $f = 0.013 \text{ d}^{-1}$ or 0.013 d^{-1} , i.e., $P = 78$ and 180 days respectively. The frequency analysis confirmed that the signals are aliases of each other, since when we subtract one of them, the other one also disappears. The alias peak is visible in the low-frequency regime of the spectral window (Figure 1, bottom panel). We should also consider that the longer period is close to the time baseline of our data. In order to disentangle the real frequency from its alias, we computed the Bayesian evidence of the two possible solutions, first allowing the period to vary between 50 and 100 days, and then between 100 and 200 days. The Bayesian evidence slightly favoured the solution with $P \sim 78 \text{ d}$, even if not with strong significance ($\Delta\ln\mathcal{Z} \simeq 2$). Since we could not definitely favour one solution over the other, we decided to perform all the subsequent analyses using both sets of parameters.

Another important outcome of our frequency search is the absence of a signal with a periodicity of ~ 16 days, that is, the transiting candidate TOI-561.03. Therefore, in order to test our ability to recover the planetary signals, we performed a series of injection/retrieval simulations, thoroughly explained in Appendix B2. The results of this injection/retrieval test are summarised in Figure 3. We found that the injected RV amplitude of .01 is not significantly affecting the retrieved value for .03, i.e. the cross-talk between the two signals is negligible. We verified that the same conclusion applies to the other signals as well. More importantly, any attempt to retrieve a null signal at the periodicity of the candidate planet .03 would result in an upper limit of $\approx 0.5 \text{ m s}^{-1}$ as we actually observe with the real dataset, when exploring the K parameter in logarithmic space. Any signal equal or higher than 1 m s^{-1} would have been detected ($> 2\sigma$), even if marginally. A signal with amplitude of 0.5 m s^{-1} would not lead to the detection of the planet (intended as a 3σ detection), but the retrieved posterior is expected to differ substantially from the observed one, especially on the lower tail of the distribution. We conclude that the planetary candidate TOI-561.03 is undetected in

Figure 3. Posterior distributions (in the top panels, the blue, red and green lines respectively) of the retrieved RV signal of TOI-561.03 according to different injected values for the RV semi-amplitudes of candidates .01 and .03. The black line in the top panels corresponds to the observed posterior of the RV semi-amplitude of candidate .03. Median and $1\text{-}\sigma$ values are marked with vertical dashed and dotted lines respectively.

Table 4. Logarithmic Bayesian evidences for the different models under exam. Model 0 corresponds to the model with no additional RVs signal other than the signals from the three transiting candidates i.e., TOI-561.01, .02, .03. Model 1, 2 and 3 correspond to the models with the three transiting candidates plus one, two and three additional planets, respectively. All the values are expressed with respect to Model 0. We note that the reported errors, as obtained from the nested sampling algorithm, are likely underestimated (Nelson et al. 2020).

	Model 0	Model 1	Model 2	Model 3
$\ln\mathcal{Z}$	0.0 ± 0.1	13.4 ± 0.2	26.1 ± 0.2	28 ± 0.2

our RV dataset, with an upper limit on the semi-amplitude of 0.5 m s^{-1} ($M_p < 2.0 M_\oplus$).

6.2 Transit attribution

Given the non-detection of the planetary candidate TOI-561.03 in the RV data, we investigated more closely the transit-like features associated with this candidate in the *TESS* light curve, at $T_0^{14} \simeq 1521.9 \text{ d}$ and $T_0 \simeq 1538.2 \text{ d}$, referred from now on as transit 1 and 4 respectively, given their sequence in the *TESS* light curve (when excluding the transits of the USP candidate). From our preliminary three-planet photometric fit (Figure A1), we noted that, with respect to the other candidates, TOI-561.03 appears to have a longer transit duration compared to the model, and the residuals show some deviations in the ingress/egress phases.

¹³ For the model with three additional signals and a quadratic trend, the calculation of the Bayesian evidence did not converge.

¹⁴ All the T_0 s in this section are expressed in BJD-2457000.

Figure 4. Transit 1 ($T_0 \approx 1521.9$ d) and 4 ($T_0 \approx 1538.2$ d) in the *TESS* detrended light curve associated with the candidate TOI-561.03. The best-fitting transit model from the three-planet model photometric fit is over-plotted (black solid line). The black dots are the data points binned over 15 minutes. With respect to transit 1, the duration of transit 4 looks underestimated by the global model, with a systematic offset in the residuals, especially in the pre-transit phase.

To better understand the cause of these deviations, we checked how the model fits each transit. As Figure 4 shows, the global model appears to better reproduce the first transit associated with TOI-561.03 (transit 1) than the second transit (transit 4), that has a duration that looks underestimated by the model. Moreover, a two-sample Kolmogorov–Smirnov statistical test¹⁵ (Hodges 1958) on the residuals of transit 1 and 4 suggests that the two residual samples are not drawn from the same distribution (threshold level $\alpha = 0.05$, statistics $KS = 0.178$, p -value $\ll 0.01$).

Therefore, we hypothesised that the two transit-like features may be unrelated, i. e., they correspond to the transits of two distinct planets. Since two additional planets are actually detected in the RV data, and their periods are longer than the *TESS* light curve interval (i. e., that *TESS* can detect, at most, only one transit for each of them), we tested

the possibility that the two transits previously associated with TOI-561.03 could indeed be due to the two additional planets inferred from the RV analysis. To check our hypothesis, we first analysed the RV dataset with a model encompassing four planets, of which only .01 and .02 have period and time of transit constrained by *TESS*. In other words, we performed the same RV analysis as described in Appendix B2, but without including TOI-561.03 in the model. We repeated the analysis twice in order to disentangle the periodicity at 78 d from its alias at 180 d, and *vice versa*. We used the posteriors of the fit to compute the expected time of transit of the outer planets. We then performed two independent fits of transit 1 and 4 with PyORBIT, following the prescriptions as specified in Section 5. We imposed a lower boundary on the period of 22 days, in order to exclude the periods that would imply a second transit of the same planet in the *TESS* light curve, and an upper limit of 200 days. As a counter-measure against the degeneracy between eccentricity and impact parameter in a single-transit fit, we kept the Van Eylen et al. (2019) eccentricity prior knowing that high eccentricities for such a compact, old system are quite unlikely (Van Eylen et al. 2019). Finally we compared the posteriors of period and time of transit from the photometric fit with those from radial velocities, knowing that the former will provide extremely precise transit times, but a broad distribution in period, while RVs give us precise periods, but little information on the transit times. The results are summarised in Figure 5: the 25.7 ± 0.3 d signal detected in the RVs is located in the vicinity of the main peak of transit 1 period distribution, while the $78.6^{+1.8}_{-2.5}$ d signal is close to the main peak in transit 4 period distribution. Moreover, Figure 5 definitely confirms that both the conjunction times inferred from the RV fit corresponding to the ~ 25 and ~ 78 days signals, respectively $T_0 = 1520^{+3}_{-6}$ d and $T_0 = 1532^{+12}_{-9}$ d, are consistent with the (much more precise) T_0 s inferred from the individual fit of transit 1 ($T_0 = 1521.885 \pm 0.004$ d) and 4 ($T_0 = 1538.178 \pm 0.006$ d) respectively. Regarding the alias at 182 ± 7 days, while the RV period is consistent with the corresponding posterior from the transit fit, the conjunction time $T_0 = 1628 \pm 13$ d that is derived from our analysis is not compatible with any of the transits in the *TESS* light curve. We also note that the proportion of the orbital period covered by the *TESS* photometry is ~ 2.3 times larger for the candidate with 78 d period, thus increasing the chance of getting a transit of it. In conclusion, taking into account both photometric and RV observations, the most plausible solution for the TOI-561 system is a four-planet configuration in which transits 1 and 4 are associated with the planets that have periods of ~ 25 d and ~ 78 d detected in the RV data, and the 180 d signal is considered an alias of the 78 d signal.

Given this final configuration, hereafter we will refer to the planets with period ~ 0.45 , ~ 10.8 , ~ 25 and ~ 78 days as planets b, c, d and e, respectively.

6.3 The system architecture

Given the presence of two single-transit planets in our data, a joint photometric and RV modelling is necessary in order to characterise the orbital parameters of all members of the TOI-561 system in the best possible way. We considered a four-planet model, with a circular orbit for the

¹⁵ We used the Python version implemented in `scipy.stats.ks_2samp`.

Figure 5. Comparison between period (left panels) and T_0 (right panels) obtained from the RV fit and from the fit of each single transit. Top and bottom panels refer to transit 1 and 4, respectively. Each panel shows the posterior distribution of the analysed parameter, and the shaded area indicates the region within the 68.27-th percentile from the mode of the distribution. The vertical solid lines indicate the inferred best-fitting value of the parameter, with thickness proportional to the associated error.

USP planet and allowing nonzero-eccentricity orbits for the others. We performed the `PyORBIT` fit as specified in Section 5, running the chains for 150 000 steps, and discarding the first 50 000 as burn-in. We summarise the results of our best-fitting model in Table 5, and show the transit models, the phase folded RVs, and the global RV model in Figures 6, 7, and 8 respectively. We obtained a robust detection of the USP planet (planet b) RV semi-amplitude ($K_b = 1.39 \pm 0.32 \text{ m s}^{-1}$), that corresponds to a mass of $M_b = 1.42 \pm 0.33 M_\oplus$, while for the 10.8 d period planet (planet c) we obtained $K_c = 1.84 \pm 0.33 \text{ m s}^{-1}$, corresponding to $M_c = 5.40 \pm 0.98 M_\oplus$. We point out that the here reported value of K_b and M_b is obtained from the joint photometric and RV fit. However, the final value of K_b and M_b that we decided to adopt (see Section 6.4 for more details) is the weighed mean between the values obtained from the joint fit reported in this section and from the floating chunk offset method described in the next section. In addition, we inferred the presence of two additional planets, with periods of 25.62 ± 0.04 days (planet d) and 77.23 ± 0.39 days (planet e), and robustly determined semi-amplitudes of $K_d = 3.06 \pm 0.33 \text{ m s}^{-1}$ ($M_d = 11.95 \pm 1.28 M_\oplus$) and $K_e = 2.84 \pm 0.41 \text{ m s}^{-1}$ ($M_e = 16.0 \pm 2.3 M_\oplus$). Both planets show a single transit in the *TESS* light curve, previously attributed to a transiting planet with period ~ 16 d, whose presence has however been ruled out by our analysis. This allowed us to infer a planetary radius of $R_d = 2.53 \pm 0.13 R_\oplus$ and $R_e = 2.67 \pm 0.11 R_\oplus$ for planet d and e respectively.

We performed the stability analysis of our determined solution, computing the orbits for 100 Kyr with the `whfast`

integrator (with fixed time-step of 0.1 d) implemented within the `rebound` package (Rein & Liu 2012; Rein & Tamayo 2015). During the integration we checked the dynamical stability of the solution with the Mean Exponential Growth factor of Nearby Orbits (MEGNO or $\langle Y \rangle$) indicator developed by Cincotta & Simó (2000) and implemented within `rebound` by Rein & Tamayo (2016). We ran 10 simulations with initial parameters drawn from a Gaussian distribution centred on the best-fitting parameters and standard deviation derived in this section. All the 10 runs resulted in a MEGNO value of 2, indicating that the family of solutions is stable.

Finally, we checked the presence of any additional signal in the RVs residuals after removing the four-planet model contribution. The GLS periodogram showed a non-significant peak at ~ 2.5 days, with a normalised power of 0.20, that is, below the 1% FAP threshold (0.26). As a supplemental confirmation, we ran a `PyORBIT` fit of the RVs, assuming first a four-planet model plus an additional signal, and then a four-planet model adding a Gaussian Process (GP) regression. For the latter approach, we employed the quasi-periodic kernel as formulated by Grunblatt et al. (2015), with no priors on the GP hyper-parameters, since we could not identify any activity-related signal in the ancillary datasets (see Section 3.3)¹⁶. In both cases, the (hyper-)parameters of the additional signal did not reach convergence, while the results for the four transiting planets were consistent with those reported above.

Considering these results, we adopt the parameters and configuration determined in this section as the representative ones for the TOI-561 system, with the only exception of the mass and semi-amplitude of TOI-561 b, that we discuss in the next section.

6.4 Alternative characterisation of the USP planet

If the separation between the period of the planet and all the other periodic signals is large enough, and the RV signal has a similar or larger semi-amplitude, it is possible to determine the RV semi-amplitude for an USP planet without any assumptions about the number of planets in the system or the activity of the host star. Under such conditions, during a single night, the influence of any other signal is much smaller than the measurement error and thus it can be neglected. If two or more observations are gathered during the same night and they span a large fraction of the orbital phase, the RV semi-amplitude of the USP planet can be precisely measured by just applying nightly offsets to remove all the other signals (e.g. Hatzes et al. 2010; Howard et al. 2013; Pepe et al. 2013; Frustagli et al. 2020 for a recent example). Such an approach, also known as floating chunk offset method (FCO; Hatzes 2014), has proven extremely reliable even in the presence of complex activity signals, as shown by Malavolta et al. (2018). In our case, the shortest, next periodic signal (i.e., TOI-561 c at 10.78 days) is ≈ 24 times the period of TOI-561 b (i.e., the USP planet at 0.45 days),

¹⁶ We are well aware that this is a sub-optimal use of GP regression, and that this approach may be justified in this specific case only as an attempt to identify additional signals.

Figure 6. *Top:* 2-minute cadence flattened light curve of TOI-561. The transits of planet b ($P \sim 0.45$ d), c ($P \sim 10.8$ d), d ($P \sim 25.6$ d), e ($P \sim 77.2$ d) are highlighted with blue, orange, red and purple triangles, respectively. *Bottom:* TOI-561 phase-folded 2-minute light curves over the best-fitting models (solid lines) for the four planets. The light curve residuals are shown in the bottom panel.

with similar predicted RV semi-amplitude, making this target suitable for the FCO approach. Thanks to our observational strategy (see Section 2.2) we could use ten different nights for this analysis. Most notably, during two nights we managed to gather six observations spanning nearly 5 hours, i.e., more than 40% of the orbital period of TOI-561 b, at opposite orbital phases, thus providing a good coverage in phase of the RV curve. We did not include RV measurements with an associated error greater than 2.5 m s^{-1} (see Appendix B1). We performed the analysis with PyORBIT as specified in Section 5, assuming a circular orbit for the USP planet and including a RV jitter as a free parameter to take into account possible short-term stellar variability and any underestimation of the errorbars. From our analysis, we obtained a RV semi-amplitude of $K_p = 1.80 \pm 0.38 \text{ m s}^{-1}$, corresponding to a mass of $M_p = 1.83 \pm 0.39 M_\oplus$. The resulting RV jitter is $j < 0.9 \text{ m s}^{-1}$ (84.13-th percentile of the posterior). We show the phase folded RVs of the USP planet in Figure 9.

Since the greater reliability of this method over a full fit of the RV dataset is counter-balanced by the smaller number of RVs, we decided not to privilege one over the other. Therefore, we assumed as final semi-amplitude and mass of TOI-561 b the weighted mean of the values obtained from the two methods (FCO approach and joint photometric and RV fit), i.e. $K_b = 1.56 \pm 0.35 \text{ m s}^{-1}$, corresponding to a mass of $M_b = 1.59 \pm 0.36 M_\oplus$. Table 5 lists the above-mentioned values for TOI-561 b.

7 COMPARISON WITH OTHER MODELS

Our final configuration is quite different from the initial one suggested by the *TESS* automatic pipeline. However, the analyses performed on the currently available data clearly disfavour the scenario with a ~ 16 d period candidate. In fact, in addition to the previous analyses, we also performed a joint photometric and RV fit assuming a five-planet model including the 16 d period candidate, and assuming that the two additional signals seen in the RVs were caused by two non-transiting planets, the inner one with period of ~ 25 d and the outer one both in the case of ~ 78 d and ~ 180 d period. Such a model, including the TOI-561.01, .02, .03 candidates plus two additional signals, corresponds to the favoured model (Model 2) identified in Section 6.1, and is therefore representative of the best-fitting solution when assuming the *TESS* candidate attribution. In fact, Table 4 suggests that in this case two additional signals need to be added to the three transiting candidates to best reproduce the RV dataset, and therefore the five-planet model should be considered also in the joint photometric and RV modelling.

According to the Bayesian evidence (Table 6), computed with the *dynesty* algorithm as specified in Section 5, the four-planet model is strongly favoured with respect to the five-planet model in both cases, with a difference in the logarithmic Bayes factor $2 \Delta \ln \mathcal{Z} \gg 10$ (Kass & Raftery 1995).

Moreover, we checked the stability of the five-planet model solutions as described in Section 6.3, with the external planet both on an orbit of 78 d and 180 d. For all the planetary parameters, including the mass of the 16 d

period planet¹⁷, we used the values and standard deviations derived from the joint photometric and RV fit, except for the inclination of the two external planets, that we fixed to 90° .

All of 10 runs yielded unstable solutions, with a close encounter or an ejection occurring within the integration time. In order to assess the origin of the instability of the system, we tested a four-planet configuration following the same procedure as above, removing one planet each time. We found that the orbital configuration of the system could be stable only if we remove the candidate with period of ~ 16 d. Therefore, the stability analysis additionally confirms our determined four-planet configuration, ruling out the presence of a ~ 16 d period planet.

8 DISCUSSION AND CONCLUSIONS

According to our analysis, TOI-561 hosts four transiting planets, including an USP planet, a ~ 10.8 d period planet and two external planets with periods of ~ 25.6 and ~ 77.2 days. The latter were initially detected in the RVs data

¹⁷ The mass of the 16 d period planet obtained from the fit was $0.62 \pm 1.03 M_\oplus$ and $1.19 \pm 1.27 M_\oplus$ for the ~ 78 d and ~ 180 d external planet period, respectively. Obviously, when selecting the 10 samples, the mass was constrained to positive values.

Table 6. Logarithmic Bayesian evidences for the models considered in Section 7. Model 0 corresponds to the four-planet model, that includes TOI-561.01, .02 and the two additional planets identified in the RVs, showing a single transit each. Model 1 and 2 correspond the five-planet model, i.e., including TOI-561.01, .02, .03 and the two additional RV planets (assumed in this case not to transit), in the case of an outer planet at ~ 78 d and ~ 180 d period respectively (see Section 6.1). All the values are expressed with respect to Model 0. We note that the reported errors, as obtained from the nested sampling algorithm, are likely underestimated (Nelson et al. 2020)

	Model 0	Model 1	Model 2
$\ln Z$	0.0 ± 0.9	-77.8 ± 1.0	-76.9 ± 1.0

only, but based on our subsequent analyses we were able to identify a single transit of each planet in the *TESS* light curve; those transits were initially associated with a candidate planet with period of ~ 16 d, whose presence we ruled out. As a ‘lesson learned’, we would suggest that caution should be taken when candidate planets, detected by photometric pipelines, are based on just two transits. In such cases, one should not hesitate to consider alternative scenarios.

TOI-561 joins the sample of 88 confirmed systems with

high precision, with a significance of $\sim 4.4\sigma$ for planet b and $> 5\sigma$ for planets c, d and e. In Figure 10 we show the position of TOI-561 b, c, d and e in the mass-radius diagram of exoplanets with masses and radii measured with a precision better than 30%. The comparison with the theoretical mass-radius curves excludes an Earth-like composition ($\sim 33\%$ iron and 67% silicates) for all planets in the system, whose internal structure we further analyse in the following sections.

8.1 TOI-561 b

The density ($\rho_b = 3.0 \pm 0.8 \text{ g cm}^{-3}$) of the USP planet is consistent with a 50% (or even more) water composition. Such a composition may be compatible with a water-world scenario, where ‘water worlds’ are planets with massive water envelopes, in the form of high pressure H_2O ice, comprising $> 5\%$ of the total mass. Even assuming the higher mass

value inferred with the FCO method ($M_b = 1.83 \pm 0.39 M_\oplus$, implying a density of $\rho_b = 3.5 \pm 0.9 \text{ g cm}^{-3}$), TOI-561 b would be located close to the 25% water composition theoretical curve in the mass-radius diagram, and it would be consistent with a rocky composition only at a confidence level greater than 2σ in both radius and mass. Given its proximity to the host star (incident flux $F_p \simeq 5100 F_\oplus$), the presence of any thick H-He envelope has to be excluded due the photo-evaporation processes that such old close-in planets are expected to suffer (e.g. Lopez 2017). Nevertheless, the possibility of a water-world scenario is an intriguing one. An H_2O -dominated composition would imply that the planet formed beyond the snow line, accreted a considerable amount of condensed water, and finally migrated inwards (Zeng et al. 2019). While the determination of the precise interior composition of TOI-561 b is beyond the scope of this work, if such an interpretation is proven trustworthy by future observational campaigns, TOI-561 b would support the hypothesis that the formation of super-Earths with a significant amount of water is indeed possible. However, an important caveat should be considered while investigating this scenario. If TOI-561 b was a water world, being more irradiated than the runaway greenhouse irradiation limit, the planet would present a massive and very extended steam atmosphere. Such an atmosphere would substantially increase the measured radius compared to a condensed water world (Turbet et al. 2020). Therefore, a comparison with the condensed water-world theoretical curves should be used with caution, since in this case it could lead to an overestimation of the bulk water content (Turbet et al. 2020).

Finally, we note that the USP planet is located on the opposite side of the radius valley, i.e. the gap in the distribution of planetary radii at $\sim 1.7\text{-}2 R_\oplus$ (Fulton et al. 2017), with respect to all the other planets in the system. The origin of the so-called radius valley is likely due to a transition between rocky and non-rocky planets with extended H-He envelopes, with several physical mechanisms proposed as explanation, i.e. photoevaporation (Chen & Rogers 2016; Owen & Wu 2017; Lopez & Rice 2018; Jin & Mordasini 2018), core-powered mass loss (Ginzburg et al. 2018; Gupta & Schlichting 2019), or superposition of rocky and non-rocky planet populations (Lee & Chiang 2016; Lopez & Rice 2018). In the TOI-561 system, planet c is located above the radius valley and it indeed appears to require a thick H-He envelope (see next section). In the same way, the compositions of planet d and e are consistent with the presence of a gaseous envelope. However, the density of TOI-561 b is lower than expected for a planet located below the radius valley, where we mainly expect rocky compositions. Moreover, TOI-561 b is the first USP planet with such a low measured density (see Figure 10). We note that also the USP planets WASP-47 e and 55 Cnc e are less dense than an Earth-like rocky planet, even if both of them have higher densities than TOI-561 b, i.e., $\rho_{\text{WASP-47e}} = 6.4 \pm 0.6 \text{ g cm}^{-3}$ (Vanderburg et al. 2017) and $\rho_{\text{55Cnc e}} = 6.3 \pm 0.8 \text{ g cm}^{-3}$ (Demory et al. 2016) respectively. Vanderburg et al. (2017) proposed the presence of water envelopes as a possible explanation for the low densities of these two planets, even though the inferred amount of water was smaller than the one required to explain TOI-561 b location in the mass-radius diagram. It should also be considered that both planets are more massive than TOI-561

b, i.e., $M_{\text{WASP-47e}} = 6.83 \pm 0.66 M_\oplus$ (Vanderburg et al. 2017) and $M_{\text{55Cnc e}} = 8.08 \pm 0.31 M_\oplus$ (Demory et al. 2016), thus increasing their chances of retaining a small envelope of high-metallicity volatile materials (or water steam) that could explain their low densities (Vanderburg et al. 2017). Given its smaller mass, this scenario is less probable for TOI-561 than for WASP-47 e and 55 Cnc e, making the object even more peculiar. With its particular properties, this planet could be an intriguing case to test also other extreme planetary composition models. For example, given the metal-poor alpha-enriched host star, the planet is likely to have a lighter core composition.

8.2 TOI-561 c, d and e

TOI-561 c, with a density of $\rho_c \sim 1.3 \text{ g cm}^{-3}$, is located above the threshold of a 100% water composition, and given its position in the mass-radius diagram we suppose the presence of a significant gaseous envelope surrounding an Earth-like iron core and a silicate mantle, and possibly a significant water layer (high-pressure ice). If the inner USP planet is water-rich, there is no simple planet formation scenario in which the outer three planets are water-poor. It is simpler to assume that all four planets were formed with similar volatile abundances, and that the inner USP planet lost all of its H-He layer, plus much of its water content, while the outer planets could keep them. Following Lopez & Fortney (2014), assuming a rocky Earth-like core and a solar composition H-He envelope, we estimate that an H-He envelope comprising $\sim 4.9\%$ of the planet mass could explain the density of TOI-561 c, using our derived stellar and planetary parameters.

Planets TOI-561 d and e are consistent with a $> 50\%$ water composition, a feature that may place them among the water worlds. However, such densities are also consistent with the presence of a rocky core plus water mantle surrounded by a gaseous envelope. We estimate that a H-He envelope of $\sim 1.8\%$ and $\sim 2.3\%$ of the planet mass could explain the observed planetary properties.

8.3 Dynamical insights

Our analysis shows that the orbital inclinations of planets c, d and e are all consistent within 1σ (see Table 5), and that the difference with the inclination of the USP planet is of the order of $\Delta i \sim 2.5^\circ$. According to the analysis of Dai et al. (2018), when the innermost planet has $a/R_\star < 5$, the minimum mutual inclination with other planets in the system often reaches values up to $5^\circ\text{-}10^\circ$, with larger period ratios ($P_c/P_b > 5\text{-}6$) implying an higher mutual inclination. Considering the large period ratio of TOI-561 ($P_c/P_b \sim 24$) and the value of $a_b/R_\star = 2.6$, the measured $\Delta i \sim 2.5^\circ$ in this case is much lower than the expected inclination dispersion of $6.7 \pm 0.7^\circ$ that Dai et al. (2018) inferred for systems with similar orbital configurations, indicating that the TOI-561 system probably evolved through a mechanism that did not excite the inclination of the innermost planet.

We also performed a dynamical N-body simulation to check if significant TTVs are expected in the TOI-561 system with our determined configuration. In fact, the period ratio of TOI-561 d and e indicates that the planets are close

to a 3:1 commensurability, hint of a second order mean motion resonance (MMR), that may suggest the presence of a strong dynamical interaction between these planets. Starting from the initial configuration (as reported in Table 5), we numerically integrated the orbits using the N-body integrator `ias15` within the `rebound` package (Rein & Liu 2012). We assumed as reference time the T_0 of the USP planet (see Table 5), that roughly corresponds to the beginning of the *TESS* observations of TOI-561. During the integration, we computed the transit times of each planet following the procedure described in Borsato et al. (2019), and we compared the inferred transit times with the linear ephemeris in order to obtain the TTV signal, reported as an observed-calculated diagram ($O - C$, Agol & Fabrycky 2018) in Figure 11. According to our simulation, TOI-561 d and e display an anti-correlated TTV signal, with a very long TTV period of ~ 4850 days (~ 13 yr), and TTV amplitudes of ~ 62 minutes (planet d) and ~ 84 minutes (planet e), calculated computing the GLS periodogram of the simulated TTVs. The anti-correlated signal demonstrates that the two planets are expected to dynamically interact (Agol & Fabrycky 2018). In contrast, the predicted TTV amplitude of planet c is extremely low (~ 0.9 min), being the planet far from any period commensurability, as well as the USP planet, which has a negligible TTV signal (< 1 sec). With the solution for the planetary system we propose in this paper, TOI-561 is a good target for a TTV follow-up, that will however require a very long time baseline in order to tackle the long-period TTV pattern. To better sample such a long-period TTV signal, it could be worth specifically re-observing the target when the deviations from the linear ephemeris are higher, i. e., during the periods corresponding to the $O - C$ peaks (or dips) in Figure 11. According to our simulation, the first peak (dip) corresponds to the period between March–December 2020, while the second one will be between January–October 2026, i. e., corresponding to the time-spans between ~ 400 – 700 and ~ 2500 – 3000 days of integration in Figure 11 respectively. We remark that this calculation is performed assuming the T_0 s inferred from single transit observations, thus implying a significant uncertainty in the TTV phase determination. Therefore, additional photometric observations are necessary to refine the linear ephemeris of the planets, and consequently also the prediction of the TTV phase.

8.4 Prospects for atmospheric characterization

Given the interesting composition of the planets in the system, we checked if the TOI-561 planets would be accessible targets for atmospheric characterisation through transmission spectroscopy, e.g. with the *James Webb Space Telescope* (*JWST*). For all the planets in the system, we calculated the Transmission Spectroscopy Metric (TSM, Kempton et al. 2018), which predicts the expected transmission spectroscopy SNR of a 10-hour observing campaign with *JWST*/Near Infrared Imager and Slitless Spectrograph (NIRISS) under the assumptions of cloud-free atmospheres, the same atmospheric composition for all planets of a given type, and a fixed mass-radius relation. We obtained TSM values of 19, 107, 24, and 14 for planets b, c, d, and e, respec-

tively. According to Kempton et al. (2018)¹⁹, this classifies TOI-561 b and c as high-quality atmospheric characterisation targets among the *TESS* planetary candidates. However, it should be noted that the TSM metric assumes rocky composition for planets with radius $< 1.5 R_{\oplus}$ and according to our analysis TOI-561 b is not compatible with such a composition. The same caveat holds for planet c, for which the assumptions under which the TSM is calculated may not be totally valid (e.g. the mass obtained from our analysis is not the same as if calculated with the Chen & Kipping (2017) mass-radius relation, that is the relation assumed in Kempton et al. (2018), and that would imply a mass of $M_c \approx 8.7 M_{\oplus}$). Therefore, this estimate of the atmospheric characterisation feasibility should be used with caution, especially as the TSM metric has been conceived to prioritise targets for follow-up, and not to precisely determine the atmospheric transmission properties.

8.5 Summary and conclusions

According to our analysis, TOI-561 hosts a nearly co-planar four-planet system, with an unusually low density USP super-Earth (planet b), a mini-Neptune (planet c) with a significant amount of volatiles surrounding a rocky core, and two mini-Neptunes, which are both consistent with a water-world scenario or with a rocky core surrounded by a gaseous envelope, and that are expected to show a strong, long-term TTV signal. The multi-planetary nature of TOI-561 offers a unique opportunity for comparative exoplanetology. TOI-561 planets may be compared with the known population of multi-planet systems to understand their underlying distribution and occurrences, and to give insights on the formation and evolution processes of close-in planets, especially considering the intriguing architecture of the system, with the presence of a uncommonly low-density USP super-Earth and three mini-Neptunes on the opposite side of the radius valley.

Considering the few available data (i. e., 2 transits for planet c, 1 transit for planets d, e), additional observations are needed to unequivocally confirm our solution. Further high-precision photometric (i. e. with *TESS*, that will re-observe TOI-561 in sector 35 – February/March 2021, or with the *CHEOPS* satellite) and RVs observations will help improving the precision on the planets parameters, both allowing for the detection of eventual TTVs and increasing the time-span of the RV dataset, that could also unveil possible additional long-period companions.

ORIGINAL UNEDITED MANUSCRIPT

APPENDIX A: PHOTOMETRIC ANALYSIS

We performed a preliminary light curve fit of the three candidate planets found by the SPOC pipeline and our independent TLS analysis, that is TOI-561.01, .02, and .03 with periods of about 10.8 d, 0.45 d, and 16.3 d, respectively. We fit the transits using PyORBIT, as specified in Section 5, but assuming circular orbits for all the candidate planets, given the uncertainty associated with the eccentricity from the analysis of *TESS* data alone (Winn 2010). We ran the chains for 100 000 steps, discarding the first 20 000 as burn-in. We list the obtained parameters in Table A1 and we show the best-fitting transit models in Figure A1. In order to test whether our light curve flattening affected the inferred parameters of the planetary candidates, we also ran the PyORBIT fit on the original PDCSAP light curve. For all the candidates, the difference between the parameters of the two runs was lower than the error on the parameters themselves, indicating that the flattening did not significantly alter the results.

We stress that, at last, our global analysis disclaimed the presence of the planetary candidate TOI-561.03, linking the transits here associated with this candidate to single transits of two additional planets discovered in the system (see Section 6).

APPENDIX B: RV ANALYSIS

B1 Removal of anomalous points

Before proceeding with a detailed analysis, we verified if any anomalous RV measurement was affecting our analysis. We followed a similar approach to that of Cloutier et al. (2019), but slightly more sophisticated due to the presence of (possibly up to) five planetary signals. Instead of analysing the power variation of the periodogram's peaks associated with the candidate planets while removing one point at the time, we decided to perform a full RV fit with the methodology described in Section 5, and to compare the resulting RV semi-amplitudes with those derived using the full dataset. To reduce computational time, we decided to remove from the dataset 5 consecutive observations at once (i. e., performing 17 iterations rather than 82), and then performed the leave-one-out cross-validation on those subsets showing deviating RV semi-amplitudes in order to identify the anomalous RV measurement. With this approach, we found out that a total of 5 RV measurements, with associated errors greater than 2.5 m s^{-1} and $S/N < 35$ were systematically producing a decrease in the semi-amplitude of candidates .01 and .02 by $\approx 0.1 - 0.2 \text{ m s}^{-1}$, and we therefore removed these points from our dataset in order to improve the accuracy of our results, even if the total variation in RV semi-amplitude was within the error bars. We note that these observations are clearly outliers at more than 2σ in both the S/N of the spectra and the RV error distributions (see Section 2.2), which is simply the consequence of having been gathered in sub-optimal weather conditions. A much simpler sigma-clipping selection would have led to the exclusion of the same data points. The complex approach we employed in this work can thus be avoided in future analysis involving HARPS-N data.

B2 RV modelling and injection/retrieval tests

Given the results of the frequency analysis in Section 6.1, we performed a PyDE+emcee RV fit with PyORBIT, following the methodology as described in Section 5, and assuming the model suggested by the Bayesian evidence computed in Section 6.1 (see Table 4), i. e. a model with the three transiting candidates plus two additional ones. We performed two independent fits, constraining the period of the outer signal to be shorter or longer than 100 days, in order to disentangle the 78 periodicity from its alias at 180 respectively. We ran the chains for 150 000 steps, discarding the first 50 000 as burn-in. The results of this analysis are reported in Tables B1 and B2.

In all our RV fits, regardless of the assumed period of the outermost planet, TOI-561.03 (i. e., the candidate with period of $\sim 16.3 \text{ d}$) remains undetected with an upper limit of $K \lesssim 0.5 \text{ m s}^{-1}$, corresponding to a rather nonphysical mass of $\lesssim 2 M_{\oplus}$ (at 1σ) for a planet with $R_p \approx 2.7 R_{\oplus}$. We thus performed a series of injection/retrieval simulations in order to assess the influence of the observational sampling and of the precision in the mass measurements of the other planets. In a first run, the synthetic datasets were simulated by assuming the orbital parameters as previously determined in the RV fits for the candidate planets .01, .02, and the non-transiting candidates, while the RV semi-amplitude of the candidate planet at 16 d was varied between 0.0 m s^{-1} and 1.5 m s^{-1} in steps of 0.5 m s^{-1} . For computational reasons, we performed this analysis only with the 78-d solution for the outer planet. We projected the model onto the real epochs of observation and then we added a Gaussian noise corresponding to the measured error plus an RV jitter of 1.0 m s^{-1} added in quadrature, while preserving the original value in the analysis. We built 50 different noise realisations and analysed each of them with the same methodology as before, i. e., PyDE+emcee through PyORBIT, but for a shorter chain length²⁰ to reduce computing time. The posteriors of each parameter were then obtained by putting together the individual posterior distributions from each noise realisation. We finally repeated the same analysis but varying the RV semi-amplitude of the candidate planet .01, i. e., the closest signal in frequency space and the one with the most uncertain RV semi-amplitude measurement other than the USP candidate, by $\pm 0.5 \text{ m s}^{-1}$ with respect to the value of 1.7 m s^{-1} used in the previous analysis.

²⁰ 10 000 steps after convergence, reached at approximately 15 000 steps.

Figure A1. *Top:* 2-minute cadence flattened light curve of TOI-561. The transits of candidates TOI-561.02 ($P \sim 0.45$ d), .01 ($P \sim 10.8$ d), and .03 ($P \sim 16.3$ d) are highlighted with blue, orange and green triangles, respectively. *Bottom:* TOI-561 phase-folded light curves over the best-fitting models (solid lines) for the three planets. The grey points are the *TESS* 2-minute data, the coloured dots are the data points binned over 15 minutes. The light curve residuals are shown in the bottom panel. Note the deviations from zero of the residuals in the ingress/egress phase for TOI-561.03.
