ABSTRACT

In a series of papers, we present a comprehensive analytic study of the global motion of growing dust grains in protoplanetary discs, addressing both the radial drift and the vertical settling of the particles. Here we study how the radial drift of dust particles is affected by grain growth. In a first step, toy models in which grain growth can either be constant, accelerate or decelerate are introduced. The equations of motion are analytically integrable and therefore the grains dynamics is easy to understand. The radial motion of growing grains is governed by the relative efficiency of the growth and migration processes which is expressed by the dimensionless parameter Λ , as well as the exponents for the gas surface density and temperature profiles, denoted by p and q , respectively. When Λ is of the order of unity, growth and migration are strongly coupled, providing the most efficient radial drift. For the toy models considered, grains pile up when $-p + q + 1/2 < 0$. Importantly, we show the existence of a second process which can help discs to retain their solid materials. For accelerating growth, grains end up their migration at a finite radius, thus avoiding being accreted on to the central star.

Key words: hydrodynamics – methods: analytical – planets and satellites: formation – protoplanetary discs – dust, extinction.

1 INTRODUCTION

Various mechanisms have been suggested to explain the formation of hundred metre-sized bodies called planetesimals found in protoplanetary discs. Goldreich & Ward (1973) proposed that planetesimals could form directly by gravitational collapse when dust settles and concentrates in the midplane. While this leads to rapid planetesimal formation, the process requires a large dust-to-gas ratio, which is prevented by the Kelvin–Helmholtz instability (Cuzzi, Dobrovolskis & Champney 1993; Garaud & Lin 2004; Chiang 2008; Barranco 2009; Lee et al. 2010a,b). Other processes have therefore been suggested, such as the streaming instability due to the collective effects of dust (Goodman & Pindor 2000; Youdin & Goodman 2005; Bai & Stone 2010a,b; Jacquet, Balbus & Latter 2011), followed by gravitational instability (Johansen et al. 2007) or turbulent concentration between eddies (Cuzzi, Hogan & Shariff 2008; Shi & Chiang 2013). Whatever the mechanism, planetesimal formation requires the presence of smaller primitive bodies called pre-planetesimals. The existence of our own Solar system

and of extrasolar planets, now commonly observed, obviously implies that at least in some protoplanetary discs pre-planetesimals can form.

Pre-planetesimals are thought to form by grain coagulation: sub-micron-sized dust particles which originated in the interstellar medium or condensed out of the newly formed nebula collide and stick under the influence of the Van der Waals interaction (e.g. Chokshi, Tielens & Hollenbach 1993; Cuzzi et al. 1993; Blum & Wurm 2008). Recent observations of protoplanetary discs (Testi et al. 2003; Apai et al. 2005; Lommen et al. 2007; Ricci et al. 2010) confirm the presence of small growing grains which can reach at least centimetre sizes (e.g. Wilner et al. 2003; Lommen et al. 2009). It has been difficult, however, to explain how grains could form bodies larger than a typical size of ten centimetres without bouncing or fragmenting (Blum & Wurm 2008; Chiang & Youdin 2010). Recently, a novel scenario which includes a realistic probability distribution function for the dust velocities overcomes this issue (Garaud et al. 2013). However, the question of the nature of the global evolution of grains in protoplanetary discs remains open.

Although the dynamics of non-growing dust grains in discs has been well studied (Weidenschilling 1977; Nakagawa, Sekiya &

★E-mail: guillaume.laibe@monash.edu

Hayashi 1986; Youdin & Shu 2002; Laibe, Gonzalez & Maddison 2012, hereafter W77, NSH86, YS02 and LGM12, respectively), numerical studies describing the evolution of growing grains are more recent (Schmitt, Henning & Mucha 1997; Stepinski & Valageas 1997; Suttner, Yorke & Lin 1999; Tanaka, Himeno & Ida 2005; Dullemond & Dominik 2005; Klahr & Bodenheimer 2006; Garaud 2007; Brauer, Dullemond & Henning 2008; Laibe et al. 2008; Birnstiel, Dullemond & Brauer 2009, 2010). Generally, for reasons of computational cost, a compromise between degrees of refinement of the disc hydrodynamics and the grain growth treatment is required: 2D or 3D studies usually have a rather crude growth model whereas works with a more sophisticated growth treatment are generally only 1D. The main result of these studies is that grain growth occurs very quickly (micron-sized particles reach centimetre sizes in a few 1000 yr). Such behaviour implies that the formation of millimetre-sized bodies in protoplanetary discs is very easy. Importantly, Brauer et al. (2008) overturned the commonly held idea that all the dust particles are accreted on to the central star once they reach a size for which the radial migration velocity is largest (the so-called ‘radial-drift barrier’). Indeed, if the growth time-scale is smaller than the migration time-scale of the grains, the growth is efficient enough for the grains to decouple from the gas before being accreted by the central star.

In our recent study (Laibe et al. 2012), we revisited the classical theory of the so-called ‘radial-drift barrier’, highlighting the role of both the drag-dominated (or A mode) and the gravity-dominated (or B mode) migration and showing that the grain pile-up efficiently prevents accretion of grains on the host star where the disc structure of observed discs is considered. YS02 already found this result for the A mode; we generalized it to the B mode, motivated by the importance of this regime when grains are growing. The results of this study therefore suggest that the radial-drift barrier may not be systematic for growing grains as well. However, the existing analytical derivations of growing grains – e.g. in Garaud (2007), Brauer et al. (2008) and Laibe et al. (2008) – are not refined enough to quantitatively constrain which discs are able to retain their grains and allow planetesimals to grow.

In a series of papers (hereafter Papers I, II, III), we study analytically the dynamics of growing grains, namely their radial drift and vertical settling. In this paper (Paper I), we focus on the radial motion of the grains, starting with toy models of grain growth. The results and the concepts introduced during this study are indeed of great help for understanding physical growth models. We introduce the equations of motion in Section 2 and consider the toy growth models in Section 3. We derive the radial evolution in the case of linear grain growth in Section 4 where we explain some fundamental features of the grain evolution. Finally, we highlight the importance of accelerating growth rates on the dust radial motion in Section 5, studying growth as a power law. Paper II extends this study to the case of realistic growth models and Paper III deals with the vertical settling of growing grains.

2 RADIAL DRIFT OF NON-GROWING GRAINS

2.1 Equations of motion

Let us first consider some important properties of the dynamics of a non-growing grain in laminar non-magnetic and non-self-gravitating protoplanetary discs (the study of a turbulent disc is beyond the scope of this paper). Grain dynamics is dominated by two forces: the central star’s gravity, which tends to make grains orbit in a Keplerian manner, and interactions with gas particles, which are

macroscopically represented by a drag force. If a dust grain has a velocity which is different to that of the gas, it experiences a drag force which tends to damp this differential velocity. The expression of the gas drag in the Epstein regime is given by

$$\begin{cases} \mathbf{F}_d = \frac{m_d}{t_s} \Delta \mathbf{v}, \\ t_s = \frac{\rho_d s}{\rho_g c_s}, \end{cases} \quad (1)$$

where m_d is the dust grain’s mass, t_s the stopping time, ρ_g the gas density, c_s the local gas sound speed, ρ_d the intrinsic dust density, s the grain size and $\Delta \mathbf{v} = \mathbf{v}_d - \mathbf{v}_g$ the differential velocity between dust and the mean gas motion. In this study, we do not consider the Stokes drag. Indeed, when solid bodies are large enough to migrate in this friction regime, they are not expected to grow by hit-and-stick collisions. However, the mathematical formalism remains the same and the results can be easily translated from one regime to the other one as in LGM12.

Seminal studies of dust dynamics were conducted by Whipple (1972), W77, Weidenschilling (1980) and NSH86, and extended by others (Takeuchi & Lin 2002; Haghighipour & Boss 2003; Garaud, Barrière-Fouchet & Lin 2004; Youdin & Chiang 2004). Here we recall the major points of those studies. The equation of motion of the grain is given by

$$\frac{d\mathbf{v}_d}{dt} + \frac{1}{t_s} (\mathbf{v}_d - \mathbf{v}_g) + \mathbf{g} = 0. \quad (2)$$

We now use the notations and the dimensionless quantities introduced in LGM12 and given in Appendix A. The radial surface density Σ and temperature \mathcal{T} profiles are described by power laws $\Sigma \propto R^{-p}$ and $\mathcal{T} \propto R^{-q}$. The physical relations are written in cylindrical coordinates (r, θ, z) . The equation of motion of such grains is given by (see LGM12)

$$\begin{cases} \frac{d\bar{v}_r}{dT} - \frac{\bar{v}_r^2}{R} + \frac{\bar{v}_r}{S_0} R^{-(p+\frac{3}{2})} e^{-\frac{Z^2}{2R^{3-q}}} + \frac{R}{(R^2+\phi_0 Z^2)^{3/2}} = 0 \\ \frac{d\bar{v}_\theta}{dT} + \frac{\bar{v}_\theta \bar{v}_r}{R} + \frac{\bar{v}_\theta - \sqrt{\frac{1}{R} - \eta_0 R^{-q} - q \left(\frac{1}{R} - \frac{1}{\sqrt{R^2+\phi_0 Z^2}} \right)}}{S_0} \\ \quad \times R^{-(p+\frac{3}{2})} e^{-\frac{Z^2}{2R^{3-q}}} = 0 \\ \frac{d^2 Z}{dT^2} + \frac{1}{S_0} \frac{dZ}{dT} R^{-(p+\frac{3}{2})} e^{-\frac{Z^2}{2R^{3-q}}} + \frac{Z}{(R^2+\phi_0 Z^2)^{3/2}} = 0, \end{cases} \quad (3)$$

where T, R, Z, S_0 are the dimensionless time, radius, height and initial grain size, respectively. These equations depend on five parameters $(\eta_0, S_0, \phi_0, p, q)$ which are the initial dimensionless acceleration due to the pressure gradient, initial grain size, initial disc aspect ratio and exponents of surface density and temperature profiles.

2.2 The Stokes number

The ratio $\frac{t_s}{t_k}$ of the drag and the Keplerian time-scales is a dimensionless parameter of the problem often called the Stokes number and frequently denoted by St:

$$\text{St} = \frac{t_s}{t_k} = \frac{s}{\frac{\rho_g c_s}{\rho_d \Omega_k}} = \frac{s}{s_{\text{opt}}} = S_0 R^p e^{\frac{Z^2}{2R^{3-q}}}, \quad (4)$$

where Ω_k is the Keplerian frequency. The size s_{opt} , which we call the optimal size for radial migration (see Fouchet et al. 2007, and Section 2), is of the order of 1 m in a Minimum Mass Solar Nebula (MMSN) and is related to the so-called ‘metre-size barrier’, first mentioned in W77, which is thought to prevent pre-planetesimal formation. However, the value of s_{opt} varies with r and depends

strongly on the disc structure, which for observed discs is very different from that of the MMSN, explaining why the term ‘radial-drift barrier’ is more appropriate.

2.3 Radial drift

When $Z = 0$, this implies

$$\text{St} = S_0 R^p. \quad (5)$$

The radial dust motion is therefore governed by the equations

$$\begin{cases} \frac{d\tilde{v}_r}{dT} = \frac{\tilde{v}_\theta^2}{R} - \frac{\tilde{v}_r}{S_0} R^{-(p+\frac{3}{2})} - \frac{1}{R^2} \\ \frac{d\tilde{v}_\theta}{dT} = -\frac{\tilde{v}_\theta \tilde{v}_r}{R} - \frac{\tilde{v}_\theta \sqrt{\frac{1}{R} - \eta_0 R^{-q}}}{S_0} R^{-(p+\frac{3}{2})}. \end{cases} \quad (6)$$

This radial motion of dust particles is a well-studied problem (W77). Because of the radial pressure gradient which counters the gravity of the central star, the azimuthal velocity of the gas is sub-Keplerian. The sub-Keplerian gas motion is the source of the differential velocity between gas and dust, which tends to be attenuated by gas drag and leads to a radial-drift motion or migration of the dust (it should not be confused with planetary migration, which has a different physical origin, namely tidal torques). Therefore, two effects control the radial motion: gas drag (whose intensity depends on St) and the sub-Keplerian motion of the gas, which produces the differential velocity and is characterized by the η_0 parameter. An expansion at small pressure gradients of order $\mathcal{O}(\eta_0)$ (see NSH86) reduces equation (6) to

$$\tilde{v}_r = -\frac{\eta_0 S_0 R^{p-q+\frac{1}{2}}}{1 + R^{2p} S_0^2} + \mathcal{O}(\eta_0^2). \quad (7)$$

Thus, depending on the value of St , the particle experiences various modes of inward drift, as stressed in LGM12.

If $\text{St} = S_0 R^p \ll 1$ (which we call the A mode, where drag dominates over gravity), particles are damped in a few stopping times, which is smaller than the orbital time-scale. The dust is then forced by the gas to orbit at a sub-Keplerian velocity, and hence cannot counter the gravity of the central star and migrates inward. This radial motion is then quickly counterbalanced by gas damping: particles migrate with a limited radial-drift velocity, which is low for the smallest grains for which the drag is strongest. If such particles have an initial radial velocity, drag circularizes their orbit in a few t_s . In the A mode, equation (7) reduces to

$$\tilde{v}_r = \frac{dR}{dT} = -\eta_0 S_0 R^{p-q+\frac{1}{2}}. \quad (8)$$

When $\text{St} = S_0 R^p \gg 1$ (which we call the B mode, where gravity dominates over drag), particles have a stopping time larger than the orbital time-scale: they orbit with an approximately Keplerian velocity. Gas drag exerts a torque which makes the particles lose angular momentum. As the angular momentum is an increasing function of the radius ($l \propto \sqrt{r}$), the dust migrates inwards. The larger the particle, the longer the response to the torque action and thus larger particles migrate at a slower rate. However, $d/dt \propto r^{-1/2}$ is a decreasing function of radius. To lose the same amount of angular momentum, grains in the inner part of the disc cover less distance than grains in the outer part: the radial-drift motion becomes less efficient as dust migrates closer to the central star. In the B mode, equation (7) reduces to

$$\tilde{v}_r = \frac{dR}{dT} = -\frac{\eta_0}{S_0} R^{-p-q+\frac{1}{2}}. \quad (9)$$

If $\text{St} \sim 1$, both previous effects combine, leading to a large radial-drift velocity: particles with such sizes migrate very efficiently on to the central star.

However, since $\text{St} = S_0 R^p$ tends to zero at small radii, the grains radial motion ends in the A mode. Integrating equation (8) gives the time at which a migrating grains reach a given radius R :

$$T(R) = \frac{1 - R^{-p+q+\frac{1}{2}}}{(-p+q+\frac{1}{2})\eta_0 S_0}. \quad (10)$$

if $-p+q+\frac{1}{2} \neq 0$ [and $T = -\ln(R)/(\eta_0 S_0)$ if $-p+q+\frac{1}{2} = 0$]. The final outcome of the grains is therefore determined by the sign of $-p+q+\frac{1}{2}$ (LGM12). This criterion determines the effect of the acceleration due to the increase of the pressure gradient which is counterbalanced by the increase of gas drag. If $-p+q+\frac{1}{2} > 0$, the dust particles are accreted on to the central star in a finite time

$$T(R=0) = \frac{1}{\eta_0 S_0 (-p+q+\frac{1}{2})}, \quad (11)$$

but if $-p+q+\frac{1}{2} \leq 0$

$$T(R) = \mathcal{O}(R^{-p+q+\frac{1}{2}}) \quad (12)$$

for small values of R and the dust particles take an infinite time to be accreted (i.e. grains pile up and survive the radial-drift barrier), or more rigorously, the time required to reach $R \rightarrow 0$ diverges as a power law. Importantly, this also means that, although the grain’s kinematics depends on the local values of the velocities, its outcome results from the integration of its global motion through the disc. Figs 1 and 2 show plots of the dust radial motion for different sizes S_0 and different signs of $-p+q+\frac{1}{2}$. For the remainder of this paper, we study grain growth and will present similar plots to Figs 1 and 2, allowing easy comparison of the effects grain growth has on the dynamics. In LGM12, we have shown that finite disc inner radii and disc lifetime only slightly mitigate this result: in a Classical T-Tauri Star disc, the grains pile-up prevents almost all the grains up to millimetre sizes in the disc from being accreted.

Figure 1. Radial motion $R(T)$ of non-growing dust grains for $\eta_0 = 10^{-2}$, $p = 0$ and $q = 3/4$ ($-p+q+\frac{1}{2} > 0$). S_0 varies from 10^{-4} to 10^2 . Top: linear scale; bottom: logarithmic scale. Grains are accreted in a finite time on to the central star.

Figure 2. Same as Fig. 1 for $p = 3/2$ and $q = 3/4$ ($-p + q + \frac{1}{2} < 0$). Grains experience a pile-up which prevents them from being accreted on to the central star. Compare the black curve of this figure with the black curve of Fig. 1 to clearly see the grain's pile-up.

3 TOY MODELS OF GRAIN GROWTH

3.1 The Stokes number

To study grain growth, we generalize the relation of equation (5) by introducing the quantity $S(T)$ defined by

$$\text{St} = SR^p, \quad (13)$$

where S corresponds to the part of the Stokes number which is related only to the grain size and does not depend on the radial coordinate. St and S are related to the physical quantities s , s_{opt} and $s_{\text{opt},0}$ via:

$$\text{St} = \frac{s}{s_{\text{opt}}}, \quad (14)$$

and

$$S = \frac{s}{s_{\text{opt},0}}. \quad (15)$$

The initial grain size is denoted as $s(t=0) = s_0$ and we define

$$S_0 \equiv \frac{s_0}{s_{\text{opt},0}} = S(T=0). \quad (16)$$

Since initially $R = 1$, we have also

$$\text{St}(T=0) = S_0. \quad (17)$$

From a practical point of view, all the equations of motion derived from the NSH86 expansion in LGM12 can be used for studying the grain growth, replacing S_0 by S since they do not depend on the grain size. The evolution of $S(T)$ has to be itself specified by a model of grain growth.

3.2 Equations of evolution

Retaining full generality, the equations of motion given by equation (6) become

$$\begin{cases} \frac{d\bar{v}_r}{dT} = \frac{\bar{v}_\theta^2}{R} - \frac{\bar{v}_r}{S(T)} R^{-(p+\frac{3}{2})} - \frac{1}{R^2} \\ \frac{d\bar{v}_\theta}{dT} = -\frac{\bar{v}_\theta \bar{v}_r}{R} - \frac{\bar{v}_\theta \sqrt{\frac{1}{R} - \eta_0 R^{-q}}}{S(T)} R^{-(p+\frac{3}{2})}. \end{cases} \quad (18)$$

The expansion with respect to η_0 does not depend on $S(T)$ and can be generalized when the grain size depends on time. Thus, substituting equation (13) into equation (7), the expression of $\frac{dR}{dT}$ becomes

$$\bar{v}_r = \frac{dR}{dT} = \frac{-\eta_0 S(T) R^{p-q+\frac{1}{2}}}{1 + R^{2p} S(T)^{2n}} + \mathcal{O}(\eta_0^2). \quad (19)$$

The remaining equation describes the evolution of $S(T)$. This can be rigorously determined from the physical growth rates (see Paper II) or prescribed by a toy model.

3.3 Toy growth models

We start to study the radial motion of growing grains using toy growth models for two reasons. First, we want to understand the impact of the grain size evolution on the dynamics independently of the radial dependence of the physical growth rate. We shall see that even with a prescribed growth rate, the dust behaviour may be rather complex. Secondly, the equation of evolution is analytically tractable. It should be noted that the toy models we shall use correspond for some specific configurations to physical growth rates (see Paper II).

The simplest toy model consists of the following linear relation:

$$S = S_0 + \gamma T. \quad (20)$$

Equation (20) is equivalent to setting:

$$s(t) = s_0 + \dot{s}_0 t, \quad (21)$$

giving

$$\gamma = \frac{\dot{s}_0}{s_{\text{opt},0}/t_{k,0}} \quad (22)$$

for the dimensionless parameter which measures the growth efficiency. Even though this model is the simplest to treat the grain growth, it cannot handle the cases of accelerating or decelerating growth. To be able to investigate what happens in those cases, we adopt a power-law prescription for the grain sizes given by

$$S(T) = \left(S_0^{1/n} + \gamma T \right)^n. \quad (23)$$

The initial size S_0 is chosen to be small enough (rigorously, $S_0 \ll \mathcal{O}(1)$) so that grains will experience all drag regimes as they grow. Indeed, varying γ modifies the growth rate and choosing $n < 1$, $n > 1$ or $n = 1$ ensures the growth slows down, speeds up or keeps a constant rate, respectively. While crude, these models allow us first to separate the effect coming from the increase of the grain size only to that due to the radial dependency of the growth model, and secondly to distinguish different dynamical evolutions for the growing grains by allowing an analytical integration of the equations of motion. Since we are considering grain growth, $\gamma > 0$.

4 THE LINEAR GROWTH REGIME

4.1 Analytic solution

For the linear growth case, we give an analytical expression for the grain size evolution which provides important information on the radial behaviour of grains. Starting from

$$\frac{dR}{dT} = \frac{-\eta_0 (S_0 + \gamma T) R^{p-q+\frac{1}{2}}}{1 + R^{2p} (S_0 + \gamma T)^2} \quad (24)$$

and setting $u = (S_0 + \gamma T)^2$ gives

$$\frac{dR}{du} = \frac{dR}{dT} \frac{dT}{du} = -\frac{\eta_0}{2\gamma} \frac{R^{p-q+\frac{1}{2}}}{1 + R^{2p}u}. \quad (25)$$

Here, the dimensionless parameter, Λ defined by

$$\Lambda = \frac{\gamma}{\eta_0}, \quad (26)$$

naturally arises from the equations. It compares the efficiency of the growth and the migration processes. Equation (25) can be rewritten as

$$\frac{du}{dR} + 2\Lambda R^{p+q-\frac{1}{2}}u = -2\Lambda R^{-p+q-\frac{1}{2}}, \quad (27)$$

which can be integrated by the method of variation of parameters. Assuming that both p and q take positive values as expected for real discs, $p + q + \frac{1}{2} > 0$ and we obtain the following expression

$$\begin{aligned} T(R) &= \frac{1}{\gamma} \left[\sqrt{u(R)} - S_0 \right] \\ &= \frac{1}{\gamma} \left[\sqrt{S_0^2 e^{\frac{2\Lambda}{p+q+\frac{1}{2}} \left(1 - R^{p+q+\frac{1}{2}}\right)} + 2\Lambda e^{-\frac{2\Lambda}{p+q+\frac{1}{2}} R^{p+q+\frac{1}{2}}} J(R)} - S_0 \right], \quad (28) \end{aligned}$$

where

$$J(R) = \int_R^1 \hat{R}^{-p+q-\frac{1}{2}} e^{-\frac{2\Lambda}{p+q+\frac{1}{2}} \hat{R}^{p+q+\frac{1}{2}}} d\hat{R} = \frac{1}{x} \int_{w^{1/x}}^1 \hat{w}^{\frac{y+1}{x}-1} e^{\frac{2\Lambda}{x} \hat{w}} d\hat{w}, \quad (29)$$

with

$$\begin{cases} x = p + q + \frac{1}{2} > 0 \\ y = -p + q - \frac{1}{2} \\ w = R^{p+q+\frac{1}{2}}. \end{cases} \quad (30)$$

While not transparent, the global behaviour of the radial motion of a growing dust grain strongly depends on $-p + q + \frac{1}{2}$ and Λ . The following considerations apply:

- If $-p + q + \frac{1}{2} \leq 0$, $J(R)$ diverges for $R \rightarrow 0$. This is the generalization for growing grains of the result found for the radial motion of non-growing grains: the slowdown due to the gas drag dominates the acceleration due to the pressure gradient, and grains fall on to the star in an infinite time.

- If $-p + q + \frac{1}{2} > 0$, the limit at $R \rightarrow 0$ is defined as $J(R)$ converges and the grains are accreted in a finite time $T_m = T(R = 0)$. Taking the limit of equation (29) at $R \rightarrow 0$ with $x > 0$ provides

$$\begin{aligned} J(0) &= \frac{1}{x} \int_0^1 \hat{w}^{\frac{y+1}{x}-1} e^{\frac{2\Lambda}{x} \hat{w}} d\hat{w} \\ &= \frac{1}{y+1} M\left(\frac{y+1}{x}, \frac{y+1}{x} + 1, \frac{2\Lambda}{x}\right), \quad (31) \end{aligned}$$

where $M(a, b, z)$ is the M-Kummer confluent hypergeometric function of indices a and b with respect to z . Thus, for $-p + q + \frac{1}{2} > 0$, the M function is defined and we obtain for different values of γ the expression of the accretion time on to the central star. Introducing $a = \frac{y+1}{x} = \frac{-p+q+\frac{1}{2}}{p+q+\frac{1}{2}}$, we find the expression of the accretion time given by

$$T_m = \frac{1}{\eta_0 \Lambda} \left[\sqrt{S_0^2 e^{\frac{2\Lambda}{x}} + \frac{2\Lambda}{ax} M\left(a, a+1, \frac{2\Lambda}{x}\right)} - S_0 \right]. \quad (32)$$

4.2 Grain radial motion

The function $\eta_0 T_m(\Lambda)$ is plotted in Fig. 3 for $S_0 = 10^{-2}$ and different pairs of (p, q) values. The main remarks on the shape of the curves are the following. We first fix the value of $-p + q + \frac{1}{2} > 0$ and vary Λ . Noting that $M(a, a+1, \frac{2\Lambda}{x}) \rightarrow 1$ when $\Lambda \rightarrow 0$, a first order Taylor expansion of equation (32) in Λ gives

$$T_m = \frac{1}{\eta_0 S_0} \left(\frac{S_0^2}{x} + \frac{1}{ax} \right) + \frac{4\Lambda}{\eta_0 x^2} f_a(S_0) + \mathcal{O}(\Lambda^2), \quad (33)$$

where

$$f_a(S_0) = \frac{1}{4} \frac{S_0^2(a+1) + 2}{S_0^2(a+1)} - \frac{1}{8} \frac{(S_0^2 a + 1)^2}{a^2 S_0^4}. \quad (34)$$

With $x = p + q + \frac{1}{2}$ and $ax = y + 1 = -p + q + \frac{1}{2}$, we recover the limit found without grain growth (see equation 34 of LGM12). Indeed, the case $\Lambda \ll 1$ corresponds to a growth time-scale that is very long compared to the migration process. Moreover, $f_a(S_0) = -\frac{1}{8a^2 S_0^4} + \mathcal{O}(S_0^{-2})$ when $S_0 \rightarrow 0$, $f_a(S_0) = \frac{1}{8} + \mathcal{O}(S_0^{-2})$

when $S_0 \rightarrow \infty$ and $f_a(S_0) = 0$ for $S_0 = \sqrt{\frac{-a+1+\sqrt{2}\sqrt{a^2+1}}{a(a+1)}}$. Thus, if the initial grain size is small enough, a small amount of growth decreases the accretion time. Indeed, growth takes the grain closer to the fast intermediate-size ($St \simeq 1$) regime of migration. On the contrary, the size of an initially large grain can only grow away from the intermediate-sized regime and growth slows down the dust radial motion.

Moreover, when $\Lambda \rightarrow \infty$, $T_m \rightarrow \infty$ due to the exponential term in the square root. More precisely,

$$T_m = \frac{e^{\frac{\Lambda}{x}} \sqrt{1 + S_0^2}}{\eta_0 \Lambda} + \mathcal{O}\left(\frac{e^{\frac{\Lambda}{x}}}{\Lambda^2}\right). \quad (35)$$

The deceleration of the migration due to the grain growth is very efficient as T_m reaches exponentially large values as Λ increases. In this case, growth is so efficient that grains only very briefly experience the $St = \mathcal{O}(1)$ regime of fast radial migration and are accreted on to the central star at very large times. As a result, for initially small grains, T_m reaches a minimum value as Λ varies.

Figure 3. Accretion time as a function of Λ , the relative efficiency of growth versus migration. Logarithmic plot of $\eta_0 T_m(\Lambda)$ for $S_0 = 10^{-3}$, $(p, q) = (0, 3/4)$, $(3/4, 3/4)$ and $(1.24, 3/4)$. The plot shows an optimal accretion time for $\Lambda = \mathcal{O}(1)$ (the migration time and the growth time have the same order of magnitude) and $-p + q + 1/2 > 0$ (no pile-up). The inset shows that $\lim_{\Lambda \rightarrow 0} \eta_0 T_m$ is indeed finite, as shown by equations (32) and (33).

The migration process is therefore optimized for a given value of $\Lambda = \frac{\gamma}{\eta_0}$, when the grain size is optimized for the migration process by the growth during the whole radial motion. This minimum is called $T_{m, \Lambda}$.

Now, if $-p + q + \frac{1}{2} \rightarrow 0$, the grain motion reaches the regime of accretion in an infinite time. As an example, the case ($p = 1.24$, $q = 3/4$) in Fig. 3, which corresponds to $-p + q + \frac{1}{2} = 0.01$, shows a large value of $T_{m, \Lambda}$ compared to the case ($p = 0$, $q = 3/4$). If $-p + q + \frac{1}{2}$ is far enough from zero, $T_{m, \Lambda} = \mathcal{O}(1)$ is reached for $\Lambda = \mathcal{O}(1)$. As an example, for ($p = 0$, $q = 3/4$), $T_{m, \Lambda} = 1.98$ for $\Lambda = 1$.

5 GROWTH AS A POWER LAW

5.1 Qualitative behaviour

We now refine the growth prescription and study the radial motion of a dust grain whose size evolution is given by the power law of equation (23). As for the case without growth (see Section 2), information about the dust behaviour can be obtained by studying the limiting cases of the A and B modes. As both S and R vary with respect to T , the related mode of migration is given by

$$\text{St}(T) = [SR^p](T). \quad (36)$$

If $\text{St} \ll 1$ (respectively $\text{St} \gg 1$), grains are in the A mode (respectively the B mode). Thus, the evolution of $R(T)$ for grains in the A mode of migration satisfies (see equation 8)

$$\frac{dR}{dT} = -\eta_0 \left(S_0^{1/n} + \gamma T \right)^n R^{p-q+\frac{1}{2}}, \quad (37)$$

and if the grain migrates in the B mode (see equation 9)

$$\frac{dR}{dT} = -\frac{\eta_0}{\left(S_0^{1/n} + \gamma T \right)^n} R^{-p-q+\frac{1}{2}}. \quad (38)$$

For clarity, we are now describing the grain motion in the (R, S) plane, non-growing grains move horizontally from right to left. The drag-dominated A mode lies below the R^{-p} curve, while the gravity-dominated B mode lies above the R^{-p} curve. As S increases with time T , the grain does not move horizontally in the (R, S) plane anymore. Consequently, the dynamics of the grain has some additional properties compared to the case without growth. Qualitatively, Fig. 4 shows various outcomes for the growing grain radial motion depending on values of Λ , n and on the initial grain size, represented by initial positions α , β (A mode) and γ (B mode) in the (R, S) plane:

(i) Case 0 ($\Lambda = 0$, initial position α): grain migrate without growing, stay in the A mode and reach the central star in a finite or infinite time, depending on the sign of $-p + q + \frac{1}{2}$.

(ii) Case 1 (Λ small, $n > 1$, initial position α): grain growth is not fast enough to reach the B mode region. Thus, grains will continue their motion towards the central star in the same stable A mode.

(iii) Case 2 (Λ large, $n > 1$, initial position α): grain growth is very efficient and it reaches the B-mode region at a given time T_1 . The growth is then so efficient that the grain will not migrate inside the critical radius R_c . Physically, the contribution of the drag integrated over the grain trajectory is too weak to dissipate all the energy and angular momentum of the grain, which is the only way to reach the central region of the disc.

(iv) Case 3 ($\Lambda \neq 0$, $n < 1$, initial position β): at the beginning of its motion, the growth is efficient enough so that the grain reaches the B-mode region at a time T_1 . However, the growth slows down

Figure 4. Trajectories of growing dust grains in the dimensionless size versus dimensionless radius plane (R, S) for three initial positions α , β and γ , which are discussed in the text. Very different behaviours are expected for these grains.

and the grain cannot sustain migration in the B mode. At a time T_2 , it returns to the A mode, where it completes its migration towards the central object.

(v) Case 4 (Λ small, $n > 1$, initial position γ): the acceleration of the grain's growth is not large enough for the B mode to be stable. The grain reaches the A mode at a time T_1 and ends its migration in the A mode.

(vi) Case 5 (Λ large, $n > 1$, initial position γ): the acceleration of the grain's growth is large enough and the B mode is stable.

In this case, we will say that this mode is stable for the grain dynamics. Mathematically speaking, we have to determine the evolution of $R(T)$ and $\text{St}(T)$ from the knowledge of $S(T)$ to describe the grain behaviour.

5.2 A mode

5.2.1 Grain evolution

To understand the grain's radial behaviour, we first study the function $R(T)$ for a grain starting in the A mode (initial positions α and β in Fig. 4). Starting from equation (37) and separating variables, a direct integration provides:

(i) If $-p + q + \frac{1}{2} \neq 0$:

$$\begin{cases} R = \left[1 - \frac{-p+q+\frac{1}{2}}{\Lambda(n+1)} \left[\left(S_0^{1/n} + \gamma T \right)^{n+1} - S_0^{\frac{n+1}{n}} \right] \right]^{\frac{1}{-p+q+\frac{1}{2}}} \\ T = \frac{1}{\eta_0 \Lambda} \left(\left[\left(1 - R^{-p+q+\frac{1}{2}} \right)^{\frac{-\Lambda(n+1)}{-p+q+\frac{1}{2}}} + S_0^{\frac{n+1}{n}} \right]^{\frac{1}{n+1}} - S_0^{1/n} \right). \end{cases} \quad (39)$$

(ii) If $-p + q + \frac{1}{2} = 0$:

$$\begin{cases} R = e^{-\frac{1}{\Lambda(n+1)} \left[\left(S_0^{1/n} + \gamma T \right)^{n+1} - S_0^{\frac{n+1}{n}} \right]} \\ T = \frac{1}{\eta_0 \Lambda} \left(\left[-\Lambda(n+1) \ln(R) + S_0^{\frac{n+1}{n}} \right]^{\frac{1}{n+1}} - S_0^{1/n} \right). \end{cases} \quad (40)$$

Thus, in the A mode, whatever the value of the growth exponent n , the grain's behaviour is the direct extension of the results found in absence of growth. If $-p + q + \frac{1}{2} \leq 0$, $\lim_{T \rightarrow +\infty} R = 0$ and the grain never reaches the star. If $-p + q + \frac{1}{2} > 0$, $\lim_{T \rightarrow T_m} R = 0$, the grain reaches the star in a finite time

$$T_m = \frac{1}{\eta_0 \Lambda} \left(\left[\frac{\Lambda(n+1)}{-p+q+\frac{1}{2}} + S_0^{\frac{n+1}{n}} \right]^{\frac{1}{n+1}} - S_0^{1/n} \right). \quad (41)$$

In this case, we study the asymptotic behaviour of T_m for small and large values of Λ . For small values of Λ , we perform a Taylor expansion of T_m to $\mathcal{O}(\Lambda)$ and obtain

$$T_m = \frac{1}{\eta_0 S_0 (-p+q+\frac{1}{2})} \left[1 - \frac{n\Lambda}{2(-p+q+\frac{1}{2}) S_0^{1+\frac{1}{n}}} \right] + \mathcal{O}(\Lambda^2). \quad (42)$$

This expression corresponds to the migration time in the absence of growth (see equation 24 of LGM12) decreased by a term proportional to the growth efficiency. For large values of Λ ,

$$T_m = \frac{1}{\eta_0} \left(\frac{n+1}{-p+q+\frac{1}{2}} \right)^{\frac{1}{(n+1)}} \Lambda^{-\frac{n}{(n+1)}} + \mathcal{O}(\Lambda^{-\frac{n}{(n+1)}-1}). \quad (43)$$

This expression of T_m does not depend on S_0 : the growth is so efficient that it erases the memory of the grain's initial size. However, one has to remember that the expression given by equation (43) is only valid in the A mode of migration.

5.2.2 Stability of the A mode

To determine if the A mode is stable or not, we now study the function $St(T)$. We study its behaviour near $T = 0$ with a Taylor expansion and in the limit at $T \rightarrow \infty$, and then find the maximum value of St compared to 1 and determine if at a given time T_1 the grain reaches the B mode. We use equations (39) or (40) and (23) to calculate $S(T)$. We first find that in the limit at large time:

- (i) if $-p + q + \frac{1}{2} > 0$, $\lim_{T \rightarrow T_m} St = 0$,
- (ii) if $-p + q + \frac{1}{2} = 0$, $\lim_{T \rightarrow +\infty} St = \lim_{T \rightarrow +\infty} \mathcal{O}(e^{-T^{n+1}} T^n) = 0$,
- (iii) if $-p + q + \frac{1}{2} < 0$, $\lim_{T \rightarrow +\infty} St = \lim_{T \rightarrow +\infty} \mathcal{O}(T^{\frac{(n+1)p}{-p+q+\frac{1}{2}}+n}) = 0$,

for $n > 0$ and both $p > 0$ and $q > 0$ (like in protoplanetary discs). Indeed, the exponent of T takes only negative values when $-p + q + \frac{1}{2} < 0$. As a result, whatever the surface density and temperature profiles, $St(T) \rightarrow 0$ at large times.

Secondly, expanding St at small times provides

$$\begin{aligned} St(T) &= S_0 + \left(S_0^{1-\frac{1}{n}} n\gamma - p\eta_0 S_0^2 \right) T + \mathcal{O}(T^2) \\ &= S_0 + \eta_0 n S_0^{1-\frac{1}{n}} (\Lambda - \Lambda_A) T + \mathcal{O}(T^2), \end{aligned} \quad (44)$$

with

$$\Lambda_A = \frac{p}{n} S_0^{1+1/n}, \quad (45)$$

Figure 5. Behaviour of the function $St(T)$ for different values of Λ for a grain originally starting its migration in the A mode. See text for details of the three cases. If the growth is efficient enough, grains are able to reach the B mode of migration.

and St , from its initial value of S_0 , increases or decreases with time depending on the sign of $\Lambda - \Lambda_A$. Thus, if $\Lambda \leq \Lambda_A$, St initially decreases with respect to time and reaches zero in a finite or infinite time. For $S_0 \sim 10^{-3}$, $\Lambda_A \sim 10^{-3}$, with $\eta_0 \sim 10^{-2}$, γ has to be smaller than 10^{-5} to be in this regime. On the other hand, if $\Lambda > \Lambda_A$, St initially increases with time before decreasing to zero, passing through a maximum at T_n . We find $St(T_n) = \mathcal{O}(\Lambda^{\frac{n}{(n+1)}})$. As a result, there exists a value $\Lambda = \Lambda_1$ (necessarily $> \Lambda_A$) such that $\Lambda_1 = \mathcal{O}(1)$ and for which $St(T_n) = \mathcal{O}(1)$. This is the limiting case for which in a time $T_1 = T_n$, $St(T_1) = St(T_n) = \mathcal{O}(1)$. The different behaviours of growing grains starting their motion in the A mode are summarized in Fig. 5. We distinguish three main behaviours:

- (i) case (i): if $\Lambda \leq \Lambda_A$: $St(T) < 1$, the A mode of migration is stable.
- (ii) case (ii): if $\Lambda_A < \Lambda \leq \Lambda_1$: the grain continues its radial motion in the stable A mode. If $\Lambda_A < \Lambda \ll 1$, $St(T_n) \ll 1$.
- (iii) case (iii): if $\Lambda > \Lambda_1$: the grain leaves the A mode of migration for the B mode. If $\Lambda \gg 1$, $St(T_n) \gg 1$, and St reaches 1 in a time $T_1 \ll T_n$ for which $St \ll 1$.

Returning to Fig. 4, the behaviour of grains 0 and 1 corresponds to cases (i) or (ii) and the behaviour of grains 2 and 3 to case (iii).

5.3 B mode

5.3.1 Grain evolution

We now study the radial motion of growing grains in the B mode of migration (i.e. $St \gg 1$) in the same way. Initially small growing grains can reach the B mode of migration at a time T_1 , where they are located at a radius R_1 and have a size S_1 (case (iii) of Fig. 5). They can also start their motion in the B mode. In this case, $S_1 = S_0$, $T_1 = 0$ and $R_1 = 1$. Starting with equation (38), a direct integration provides:

(i) if $n \neq 1$:

$$\left\{ \begin{aligned} R &= \left[R_1^{p+q+\frac{1}{2}} - \frac{p+q+\frac{1}{2}}{\Lambda(1-n)} \left[(S_1^{1/n} + \gamma T_1)^{1-n} \right. \right. \\ &\quad \left. \left. - (S_1^{1/n} + \gamma T_1)^{1-n} \right] \right]^{\frac{1}{p+q+\frac{1}{2}}}, \\ T &= \frac{1}{\eta_0 \Lambda} \left[\left[\left(R_1^{p+q+\frac{1}{2}} - R^{p+q+\frac{1}{2}} \right) \frac{\Lambda(1-n)}{p+q+\frac{1}{2}} \right. \right. \\ &\quad \left. \left. + (S_1^{1/n} + \gamma T_1)^{1-n} \right]^{\frac{1}{1-n}} - S_1^{1/n} \right]. \end{aligned} \right. \quad (46)$$

(ii) if $n = 1$:

$$\left\{ \begin{aligned} R &= \left[R_1^{p+q+\frac{1}{2}} - \frac{p+q+\frac{1}{2}}{\Lambda} \ln \left(\frac{S_1 + \gamma T}{S_1 + \gamma T_1} \right) \right]^{\frac{1}{p+q+\frac{1}{2}}}, \\ T &= \frac{1}{\eta_0 \Lambda} \left[(S_1 + \gamma T_1) e^{\frac{\Lambda \left(R_1^{p+q+\frac{1}{2}} - R^{p+q+\frac{1}{2}} \right)}{p+q+\frac{1}{2}}} - S_1 \right]. \end{aligned} \right. \quad (47)$$

For simplicity, we now consider only the case of $p + q + \frac{1}{2} > 0$ (the exponent of R in equations 46 and 47), which is the case in real nebulae. Here, contrary to the A mode, the asymptotic behaviour of $R(T)$ depends on the value of $n > 0$. If $n \leq 1$, $\lim_{T \rightarrow T_m} R = 0$ (weak growth). If $n > 1$, two cases arise. First, if $\Lambda \leq \frac{(p+q+\frac{1}{2})(S_1^{1/n} + \gamma T_1)^{1-n}}{R_1^{p+q+\frac{1}{2}}(n-1)} = \Lambda_c$, $\lim_{T \rightarrow T_m} R = 0$ (weak growth). Secondly, if $\Lambda > \Lambda_c$, $\lim_{T \rightarrow +\infty} R = R_c$, the grain asymptotically approaches a radius

$$R_c = R_1 \left(1 - \frac{(p + q + \frac{1}{2}) (S_1^{1/n} + \gamma T_1)^{1-n}}{R_1^{p+q+\frac{1}{2}} (n-1) \Lambda} \right)^{\frac{1}{p+q+\frac{1}{2}}} \quad (48)$$

(intense growth).

5.3.2 Stability of the B mode

To determine in which case the B mode is stable, we study the asymptotic behaviour of $St(T)$ for small and large Λ . First, in the limit at large time:

(i) For weak growth (if $n \leq 1$ or $n > 1$ and $\Lambda \leq \Lambda_c$): $\lim_{T \rightarrow T_m} St = 0$. Consequently, whatever the initial evolution of St , there is a time T_2 for which the grain switches to the A mode: the B mode of migration is unstable. This situation corresponds to trajectories 3 and 4 of Fig. 4.

(ii) For strong growth (if $n > 1$ and $\Lambda > \Lambda_c$): $\lim_{T \rightarrow +\infty} St = +\infty$. In this case, the growth is efficient, like for trajectory 5 of Fig. 4: the grain cannot drift inwards past a critical radius R_c .

Secondly, expanding St at times close to T_1 provides

$$\begin{aligned} St &= R_1^p (S_1^{1/n} + \gamma T_1)^n + \Lambda R_1^p (S_1^{1/n} + \gamma T_1)^{n-1} \\ &\quad \times \left(n\gamma - \frac{\gamma p}{\Lambda R_1^{p+q+\frac{1}{2}}} (S_1^{1/n} + \gamma T_1)^{-n+1} \right) (T - T_1) \\ &\quad + \mathcal{O}((T - T_1)^2) \end{aligned}$$

$$\begin{aligned} &= R_1^p (S_1^{1/n} + \gamma T_1)^n + R_1^p (S_1^{1/n} + \gamma T_1)^{n-1} \\ &\quad \times n\eta_0(\Lambda - \Lambda_B)(T - T_1) + \mathcal{O}((T - T_1)^2), \end{aligned} \quad (49)$$

where

$$\Lambda_B = \frac{p (S_1^{1/n} + \gamma T_1)^{1-n}}{R_1^{p+q+\frac{1}{2}}}, \quad (50)$$

and St , from its value of S_1 at T_1 , increases or decreases with time depending on the sign of $\Lambda - \Lambda_B$. Thus, if $\lim_{T \rightarrow T_m} St = 0$ and $\Lambda < \Lambda_B$, $St(T)$ is initially decreasing and tends to zero at large times. If $\lim_{T \rightarrow T_m} St = 0$ and $\Lambda > \Lambda_B$, St is initially increasing, reaches a maximum value and tends to zero at large times. If $\lim_{T \rightarrow +\infty} St = +\infty$ and $\Lambda < \Lambda_B$, St is initially decreasing, reaches a minimum value at a time T_n and tends to infinity at large times. There exists a value $\Lambda = \Lambda_2$ (necessarily $< \Lambda_B$), for which $St(T_n) = 1$. Thus, if $\Lambda < \Lambda_2$, $St(T_n) < 1$ and if $\Lambda > \Lambda_2$, $St(T_n) > 1$. If $\lim_{T \rightarrow +\infty} St = +\infty$ and $\Lambda > \Lambda_B$, $St(T)$ is initially increasing and tends to infinity at large times.

The different behaviours of growing grains experiencing a radial motion in the B mode are summarized in Fig. 6. We distinguish five main behaviours:

(i) case $(i)_w$: weak growth and $\Lambda < \Lambda_B$: St decreases and the B mode is unstable.

(ii) case $(ii)_w$: weak growth and $\Lambda \geq \Lambda_B$: St increases and then decreases as it tends to zero, the B mode is thus unstable. Therefore, whatever the value of Λ , the grain will always reach the A mode.

(iii) case $(i)_i$: intense growth and $\Lambda < \Lambda_2$: even though St reaches values large enough at large time, its initial decrease due to small values of Λ leads to a transition to the A mode.

(iv) case $(ii)_i$: intense growth and $\Lambda_2 \leq \Lambda < \Lambda_B$: even if St decreases at small times, Λ is large enough for the grain to stay in the B mode.

(v) case $(iii)_i$: intense growth and $\Lambda \geq \Lambda_B$: St increases and the B mode is stable.

Returning to Fig. 4, the behaviour of grains 3 and 4 corresponds to cases $(i)_w$ and $(ii)_w$, for which the B mode is unstable, and the

Figure 6. Behaviour of the function $St(T)$ for different values of Λ for a grain originally starting its migration in the B mode. The five behaviours are described in the text. An efficient growth is required to maintain the particle in the B mode.

behaviour of grains 2 and 5 corresponds to cases (ii)_i and (iii)_i, for which the B mode is stable.

5.4 Combining A and B modes

The radial behaviour of initially small growing grains for the different values of the parameters can now be interpreted and a summary is presented in Fig. 7. If $\Lambda \leq \Lambda_A$, or if $\Lambda_A < \Lambda \leq \Lambda_1 = \mathcal{O}(1)$, the growth is not efficient enough to reach the B mode of migration and the A mode is stable. The dust behaviour at large times depends on the value of $-p + q + \frac{1}{2}$ (as for non-growing grains, which ultimately migrate in the A mode). If $-p + q + \frac{1}{2} > 0$, the radial-drift efficiency is increased by growth and the particle is accreted in a finite time which decreases with Λ . If $-p + q + \frac{1}{2} \leq 0$ the particle reaches the inner region of the disc, but will never be accreted on to the central object.

If $\Lambda > \Lambda_1$, the growth is efficient enough and the A mode is unstable. The grain reaches the B mode at a rate that depends on Λ . For weak growth, or for intense growth with $\Lambda < \Lambda_2$, the B mode is unstable and the particle reaches the A mode again. However, the new value of Λ_1 which determines the stability of this migration in the A mode depends of the new initial position in the disc. If Λ_1 remains small enough, an oscillation between the two modes may occur until St is large enough. Then, the A mode will be stable as Λ_1 reaches large enough values. Again, the final grain behaviour depends on $-p + q + \frac{1}{2}$. For intense growth with either $\Lambda_2 \leq \Lambda < \Lambda_B$ or $\Lambda \geq \Lambda_B$, the growth is very efficient. The B mode is stable and the particles converge to a limit radius R_c in an infinite time. In this case, the fact that the particle is not accreted on to the central star does not depend on the profile effect (described in LGM12, and mentioned in Section 2) as for a weak growth process, but on the ‘growth effect’, which is defined by the value of Λ .

Finally, the results of the analysis we performed analytically in this section are confirmed by a direct integration of the equations of motion in Appendix B.

6 CONCLUSIONS AND PERSPECTIVES

We have studied the impact of grain growth on to the radial motion of grains in protoplanetary discs using two toy models: a linear and a power law of grain growth. We found the following.

- (i) Depending on the relative efficiency between growth and migration which is given by the value of the dimensionless parameter Λ , three behaviours are possible for the radial motion of the dust grains. If $\Lambda \ll 1$, the impact of the growth on the migration consists only of a slowly varying correction compared to the case without any growth. Conversely, for $\Lambda \gg 1$, the migration is efficiently slowed down by the growth. Indeed, grains spend a relatively little time in the regime where $St = \mathcal{O}(1)$ and become more and more decoupled from the gas as they grow. Thus, the migration occurs on a time-scale much longer than that without any growth since the time where the particle stays in the regime $St = \mathcal{O}(1)$ is negligible. For the intermediate case – i.e. $St = \mathcal{O}(1)$ – the growth and the migration are occurring together, leading to efficient radial drift.
- (ii) The final outcome of the grain’s radial migration is, however, a result of its global motion through the disc. The grains experience a pile-up from the competition between the drag and the increasing pressure gradient if $-p + q + 1/2 \leq 0$. If the grain does not experience any pile-up, there exists a value of Λ such that $\Lambda = \mathcal{O}(1)$ – i.e. a critical value for migration $\gamma = \mathcal{O}(\eta_0)$ – which minimizes the time for the grain to reach the central star.
- (iii) In addition to the standard grain pile up close to $R = 0$ which occurs for non-growing grains, the discs can retain solid material with a high growth efficiency. Indeed, for $n > 1$, the particle can

Figure 7. Summary of the global evolution of an initially small growing grain. For intense accelerating growth, particles decouple from the gas at a finite radius, staying in the B mode of migration. Otherwise, grains survive the radial-drift barrier if they pile-up, i.e. if $-p + q + 1/2 \leq 0$ since they migrate in the A mode. The grains radial migration is always more efficient when the ratio between growth and migration time-scales is of the order of unity.

end its migration in the B mode and converges in an infinite time to a finite radius R_c . This growth effect happens when the grain size increases so quickly that the integrated contribution of the drag cannot dissipate either the grain energy or its angular momentum.

(iv) Allowing the growth to accelerate or decelerate enriches the grains' possible behaviours. As shown in Fig. 7, we distinguish four regimes for the radial motion of growing dust grains: (1) accretion enhanced by growth, (2) accretion slowed down by growth, (3) no accretion by traditional pile up and (4) no accretion by decoupling at a finite radius, depending on the sign of $-p + q + \frac{1}{2}$, and the values of Λ and n .

While useful, these toy growth models are not sufficient to quantitatively predict the behaviour of the grains in protoplanetary discs since the growth rate of the particles does not depend on the radial position of the grains. This assumption is incorrect for physical growth models. In this case, the growth and the radial drift of the grain interact and the grain dynamics may be complicated. This issue is addressed in Paper II.

APPENDIX A: NOTATIONS

The notations and conventions used throughout this paper are summarized in Table A1.

Table A1. Notations used in the article.

Symbol	Meaning
M	Mass of the central star
g	Gravity field of the central star
r_0	Initial distance to the central star
ρ_g	Gas density
$\bar{\rho}_g(r)$	$\rho_g(r, z = 0)$
c_s	Gas sound speed
$\bar{c}_s(r)$	$c_s(r, z = 0)$
c_{s0}	Gas sound speed at r_0
T	Dimensionless time
\mathcal{T}	Gas temperature (T_0 : value at r_0)
Σ_0	Gas surface density at r_0
p	Radial surface density exponent
q	Radial temperature exponent
P	Gas pressure
v_k	Keplerian velocity at r
v_{k0}	Keplerian velocity at r_0
H_0	Gas scale height at r_0
ϕ_0	Square of the aspect ratio H_0/r_0 at r_0
η_0	Sub-Keplerian parameter at r_0
s	Grain size
S	Dimensionless grain size
S_0	Initial dimensionless grain size
St	Stokes number
y	Grain size exponent in the drag force
v_g	Gas velocity
v	Grain velocity
ρ_d	Dust intrinsic density
m_d	Mass of a dust grain
t_s	Drag stopping time
t_{s0}	Drag stopping time at r_0

APPENDIX B: RADIAL EVOLUTION WITH THE POWER-LAW TOY MODEL

To compare this analysis for the evolution directly obtained from the equation of motion, we integrate numerically equation (18) for different values of the parameters η_0 , S_0 , p , q , γ and n . We set the dimensionless acceleration due to the pressure gradient $\eta_0 = 10^{-2}$ to mimic a real nebula and an initial size $S_0 = 10^{-3}$ to start with grains small enough (like in the planet formation process) so as to initially have $St \ll 1$. We verify that with $S_0 = 10^{-4}$ or 10^{-2} the results do not significantly change. We then explore the parameter space by first varying the order of magnitude of γ from 10^{-4} to 10^2 and second setting $n = 0.5, 1, 2$ so as to treat one convex, one linear and one concave evolution of $St(T)$. Thus, $7 \times 3 = 21$ trajectories are computed for each of the nine (p, q) pairs formed by $p = 0, 3/4, 3/2$ and $q = 1/2, 3/4, 1$.

To show how growth affects the radial grain motion, we focus on the two cases: $(p = 0, q = 3/4)$ and $(p = 3/2, q = 3/4)$, shown in Figs B1 and B2, which we analysed in absence of grain size evolution in LGM12. We note that a large class of migration regimes occur, depending on the growth parameters γ and n . The following major behaviours can be highlighted.

Figure B1. Radial motion $R(T)$ of dust grains for $\eta_0 = 10^{-2}$, $S_0 = 10^{-3}$, $p = 0$, $q = 3/4$, and values of γ ranging from 10^{-4} to 10^2 in linear (top panel) and logarithmic scale (bottom panel). From top to bottom in each panel: $n = 0.5, 1$ and 2 .

Figure B2. Same as Fig. B1 for $p = 3/2$ and $q = 3/4$.

(i) When varying γ while fixing all the other parameters, migration to the inner regions is optimal for a value which depends on p , q and n and is close to 10^{-2} . With $\eta_0 = 10^{-2}$, this corresponds to $\Lambda = 1$. The corresponding migration time for R to reach 0 is of the order of $10^2 = \eta_0^{-1}$, which agrees with the result found above (see Fig. 3, which is only valid for $n = 1$, or equation 41). When $\gamma \geq 1$, the grain migrates slowly to the central star or to the limit radius, R_c , as predicted by equation (48).

(ii) When increasing n while fixing all the other parameters, migration at small and large values of γ is less efficient.

(iii) When comparing the case $p = 3/2$ ($-p + q + \frac{1}{2} < 0$) and the case $p = 0$ ($-p + q + \frac{1}{2} > 0$) while fixing all the other parameters, the dust dynamics is modified by the grains pile-up. For example, comparing the cases at $\gamma = 10^{-2}$, even with different values of n for each value of p , the particle is accreted on to the central star in a finite time for $-p + q + \frac{1}{2} > 0$, but only migrates slowly to the disc inner regions for $-p + q + \frac{1}{2} < 0$ (the curvature of the trajectory becomes convex at large time).

Thus, the results obtained from the equation of motion confirm the prediction performed from (1) the small pressure gradient and (2) the A- and B-mode expansions. It is also important to note that the grain's radial trajectories are given in dimensionless coordinates. In some cases (for example $p = 3/2, q = 3/4, \eta_0 = 10^{-2}, \gamma = 10^{-2}$,

see the black curve in Fig. B2), the particle drastically slows down between $R = 0.05$ for $n = 0.5$ and $R = 0.1$ for $n = 2$ because of the profile effect. This corresponds to 10 au for a grain which starts to migrate at 200 au, which is still relevant for planet formation. Moreover, even if the accretion time on to the central star is finite, the accretion process can be long enough, especially for large values

of Λ or values of $-p + q + \frac{1}{2}$ close to zero to allow particles to grow in real nebulae before the disc disappears.
