ABSTRACT

We aim to derive a simple analytic model to understand the essential properties of vertically settling growing dust grains in laminar protoplanetary discs. Separating the vertical dynamics from the motion in the disc mid-plane, we integrate the equations of motion for both a linear and an exponential grain growth rate. Numerical integrations are performed for more complex growth models. We find that the settling efficiency depends on the value of the dimensionless parameter γ, which characterizes the relative efficiency of grain growth with respect to the gas drag. Since γ is expected to be of the same order as the initial dust-to-gas ratio in the disc (∼10−2), grain growth enhances the energy dissipation of the dust particles and improves the settling efficiency in protoplanetary discs. This behaviour is mostly independent of the growth model considered as well as of the radial drift of the particles.

Key words: hydrodynamics – methods: analytical – planets and satellites: formation – protoplanetary discs.

1 INTRODUCTION

In this series of papers, we study the dynamics of growing dust grains in protoplanetary discs. In the two previous papers (Laibe et al. 2013a,b, hereafter Paper I and Paper II, respectively), we have shown how grain growth interplays with the radial drift of the grains and can lead to situations where the dust particles are accreted on to the central star (the so-called radial-drift barrier) or survive in the disc. These studies assumed that the radial and the vertical motion of grains can be decoupled since they occur on very different time-scales. Grains radial drift was therefore derived as if the grains motion occurred only in the disc mid-plane.

However, in addition to their radial evolution, grains experience a vertical motion that results from the balance between the vertical component of the central star’s gravity and of the gas drag. Dust particles settle more or less efficiently to the mid-plane of the disc depending on their size. This motion is therefore called vertical settling. By definition, vertical settling consists of the dust motion in a laminar flow. When the disc is turbulent, the particles are stirred out of the disc mid-plane in a process called vertical stirring. However, turbulence is not a purely diffusive noise since turbulent fluctuations are correlated. Studying laminar flows is therefore important, as it provides the limit at infinitely large correlation times.

The vertical settling of grains with constant sizes has been studied theoretically in various papers (see e.g. Garaud, Barrière-Fouchet & Lin 2004; Barrière-Fouchet et al. 2005). Vertical dust evolution depends essentially on the $s/\sqrt{\phi}$ ratio ($\phi$ being the optimal size of migration introduced in Paper I) but weakly on the ratio $\phi$ between the scaleheight $H$ and radius $r$, since $\phi$ is in a range of $10^{-2}$–$10^{-1}$ for cold protoplanetary discs. The dynamics of large grains is driven by two time-scales: a typical settling time equal to the stopping time $t_s$, which characterizes the response time of a grain to the gas drag, and a pseudo-period of oscillations about the mid-plane which is of order $t_{\phi}$, the Keplerian time-scale. Mid-sized grains have a typical settling time of $t_{\phi} \simeq t_s$ (thus, the settling occurs in approximately one orbit). Two time-scales can also be distinguished for the vertical motion of small grains: the stopping time $t_s$ and the typical settling time $t_s^2/t_{\phi}$, which increases for decreasing grain sizes. Fastest sedimentation occurs for the critical regime, i.e. for $t_{\phi} \simeq t_s$. This regime corresponds to a typical grain size of 1 m at 1 au in the theoretical minimum mass solar nebula model and 1 cm at 50 au in observed classical T-Tauri star discs.

The vertical settling of dust is strongly affected by grain growth. In this paper, we aim to quantify the efficiency of the vertical settling of growing dust grains. Although the study is instructive and simple in comparison to the one on the radial evolution, we have not found any analytic results on the topic in the literature. We first recall the main properties of the settling of non-growing grains in Section 2. We then generalize the harmonic oscillator approximation for non-growing grains, which we integrate analytically for...
both a linear and an exponential growth model, as well as numerically for other physical growth models. The results are shown to be mainly independent of the growth model considered. Moreover, the studies of both the radial and vertical motion of growing grains performed, respectively, in Papers I, II and in this paper are based on the assumptions that the motions in the disc mid-plane and in the vertical direction are decoupled. We test the validity of this assumption in Section 4 and present our conclusions in Section 5.

2 VERTICAL SETTLING OF NON-GROWING GRAINS

The disc is a thin, non-magnetic, non-self-gravitating, inviscid perfect gas disc which is vertically isothermal. Its radial surface density and temperature are described by power-law profiles. The flow is laminar and in stationary equilibrium. Consequently, the gas velocity and density are described by well-known relations, which we presented in Paper I. Notations are described in Appendix A. The flow is an effective gas disc which is vertically isothermal. Its radial surface density and temperature are described by power-law profiles. The flow is laminar and in stationary equilibrium. Consequently, the gas velocity and density are described by well-known relations, which we presented in Paper I. Notations are described in Appendix A.

Here we derive approximate solutions for the vertical motion of the dust particles, the three characteristic regimes of grain dynamics on the cylindrical axis is given by the following Lienard equation:

\[
\frac{d\phi}{dt} = \frac{R e^{-\phi t} + \frac{1}{2} T R^{-\phi t}}{R} = 0.
\]

These equations depend on five control parameters \((\eta_0, S_0, \phi_0, p, q)\) which are the initial dimensionless accelerations due to the pressure gradient, initial dimensionless grain size, initial disc aspect ratio and exponents of surface density and temperature profiles, respectively.

To approximate solutions for the vertical motion of dust grains. This motion depends on the radial distance from the central star and is thus coupled to the grains radial evolution. However, its general behaviour is well reproduced by separating both radial and vertical motions (i.e. all quantities are taken at \(r = r_0\), i.e. \(R = 1\), see below for the justification). The equation of grain dynamics on the cylindrical axis is given by the following Lienard equation:

\[
\frac{d\phi}{dt} + \frac{e^{\phi} T S_0}{2} R e^{-\phi t} + \frac{Z}{2 R e^{-\phi t}} = 0.
\]

To \(O(\phi_0^2)\) (for a thin disc) and \(O(Z^2)\) (for particles close to the disc mid-plane), or equivalently, performing a linear expansion of this equation near its fixed point \((\phi = 0, Z = 0)\) this becomes

\[
\frac{d\phi}{dt} + \frac{e^{\phi} T S_0}{2} R e^{-\phi t} + \frac{Z}{2 R e^{-\phi t}} = 0.
\]

which implies that near this fixed point, grain dynamics are equivalent to the damped harmonic oscillator. Fig. 1 compares the vertical motion of the dust particles given the harmonic oscillator approximation (equation 3) and the general case (equation 2), and show that the harmonic oscillator approximation is justified. Moreover, given the sizes \(S_0\) of the dust particles, the three characteristic regimes of the damped harmonic oscillator can then be distinguished as follows:

(i) \(S_0 > 1/2\): underdamped oscillator

\[
Z(T) = e^{-\frac{Z}{T S_0}} [A \cos(\lambda T) + B \sin(\lambda T)]
\]

\[
\lambda = \sqrt{1 - \left(\frac{1}{2 S_0}\right)^2},
\]

\[
A = Z(0)
\]

\[
B = \frac{1}{\lambda} \left(\frac{1}{2 S_0} Z(0) + \dot{Z}(0)\right).
\]

(ii) \(S_0 = 1/2\): critical regime

\[
Z(T) = (A + BT) e^{-\frac{Z}{T S_0}}
\]

\[
A = Z(0)
\]

\[
B = Z(0) + \dot{Z}(0).
\]

(iii) \(S_0 < 1/2\): overdamped oscillator

\[
Z(T) = A e^{\lambda_+ T} + B e^{\lambda_- T}
\]

\[
\lambda_\pm = -\frac{1}{2 S_0} \pm \sqrt{\left(\frac{1}{2 S_0}\right)^2 - 1},
\]

\[
A = Z(0) + \frac{1}{\lambda_-} Z(0) - \frac{1}{\lambda_+} Z(0)
\]

\[
B = -\frac{1}{\lambda_-} Z(0) + \frac{1}{\lambda_+} Z(0).
\]

The vertical settling of a grain occurs on a dimensionless time-scale that is shorter than the migration time-scale. From equation (6) (respectively, equation 4), for small (respectively, large) grains, the dimensionless settling time is \(1/S\) (respectively, \(S\)). The fastest sedimentation occurs for the critical regime, i.e. for \(S = 1/2\) (equation 5). A good approximation for the typical settling time \(T_{set}\) is therefore

\[
T_{set} \simeq 1 + \frac{S^2}{S}.
\]

Figure 1. Vertical motion of a non-growing dust particle starting at \(Z_0 = 1\) with \(S_0 = 10^{-2}\) (top), \(S_0 = 1\) (centre) and \(S_0 = 10^2\) (bottom) obtained by numerical integration. The solid lines represent the damped harmonic oscillator motion (equation 3) and dashed lines the general case (equation 2) for \(\phi_0 = 0.01\). Note the different time-scale in the centre plot.
The typical migration time is obtained from equation 16 of Laibe, Gonzalez & Maddison (2012) estimating $R/ \partial y/\partial t$ at $R = 1$, providing

$$T_{\text{mig}} \approx \frac{1 + S^2}{\eta_0 S},$$  \hspace{1cm} (8)

$$T_{\text{set}}/T_{\text{mig}} = \mathcal{O}(\eta_0) \approx 10^{-2},$$

settling is almost a hundred times faster than migration and both the vertical and the radial motion are decoupled (Garaud et al. 2004).

### 3 VERTICAL SETTLING OF GROWING GRAINS

#### 3.1 Growth models

In the case of growing grains, the ratio $\frac{S}{T}$ of the drag ad the Keplerian time-scales evolves, changing the vertical evolution of the particles. Following the same format as in Papers I and II and the notations in Appendix A, we have

$$S(T) = \frac{S_0}{h_c} = \frac{s}{s_{\text{opt}}} = S(T) R^\nu e^{\frac{S^2}{2}} $$  \hspace{1cm} (9)

where $\Omega_k$ is the Keplerian frequency and $c_s$, $\rho_g$, $\rho_d$ the gas sound speed, the gas density and the dust density, respectively. As with the settling of non-growing grains, we assume first that the vertical motion occurs much faster than the radial motion, implying that $R = 1$ during the grain's settling and secondly, we assume that the oscillations are sufficiently close to the disc mid-plane ($Z \ll 1$) during the evolution. For non-growing grains, we have seen that these assumptions have a negligible impact on the vertical evolution. Thus, equation (9) reduces to

$$S(T) = S(T).$$  \hspace{1cm} (10)

Substituting $S_0$ by $S$ in equation 3 provides the differential equation which governs the vertical motion of the grains:

$$\dot{Z} + \frac{1}{S(T)}\ddot{Z} + Z = 0.$$  \hspace{1cm} (11)

The evolution of $S(T)$ is governed by the growth rate of the particles. Several models of grain growth have been introduced and studied in Paper II. Importantly, it is explained that for a cold disc at $Z \ll 1$ the growth rate of the particles is of the form

$$\frac{dS}{dT} = \gamma f(S),$$  \hspace{1cm} (12)

where $f$ is a function of the grain size which depends on the models for the relative turbulent velocities between the particles and the scaleheight of the dust layer considered. As discussed in Paper II, $\gamma$ is of order $\epsilon_0$, the initial dust-to-gas ratio of the disc, which is $\approx 10^{-2}$ in protoplanetary discs. With the most recent models of dust and gas turbulence modelling (see Paper II for a discussion), $f$ is of the form

$$f(S) = \frac{S}{1 + S} \simeq S^{y_g},$$

with $y_g = 1$ for $S \ll 1$ and $y_g = 0$ for $S \gg 1$. $f$ often reduces to a simple power law of exponent $y_g$ when treating the small and the large grains separately. In this case, as discussed in Paper II, $y_g$ can take values of order unity in the case of realistic growth rates and differs from the case $S \ll 1$ to the case $S \gg 1$. The size evolution is thus given by

$$S(T) = \left(1 + y_g \right)\gamma T + S_0^{-y_g+1},$$  \hspace{1cm} (13)

if $y_g \neq 1$ and

$$S(T) \approx S_0 e^{\gamma T},$$  \hspace{1cm} (14)

if $y_g = 1$. The case $y_g = 0$ (linear growth, equation 19 of Paper I) corresponds to the limit of the large grains in equation (13) and the case $y_g = 1$ to the limit of the small grains. It is also straightforward to derive the general expression of the size evolution to the power-law toy model (equation 23) used in Paper I.

#### 3.2 Linear growth model

We investigate the coupling between the growth and the settling using the simplest linear growth model from equation (14) with $y_g = 0$ giving

$$\dot{Z} + \frac{1}{S_0 + \gamma T} \dot{Z} + Z = 0.$$  \hspace{1cm} (15)

To solve this differential equation, we introduce the auxiliary function $\xi(T)$ such that

$$Z(T) = \xi(T) \times e^{-\frac{1}{S_0 + \gamma T} \frac{S^2}{2}} = \xi(T) \times \left(1 + \frac{\gamma T}{S_0}\right)^{-\frac{1}{2}}.$$  \hspace{1cm} (16)

Hence, $Z(T)$ is the product of two functions: $(1 + \frac{\gamma T}{S_0})^{-\frac{1}{2}}$ and a function $\xi(T)$ which satisfies

$$\ddot{\xi} + I(T) \dot{\xi} = 0,$$  \hspace{1cm} (17)

with

$$I(T) = 1 - \frac{1}{4} \left(1 + \gamma T \right)^2.$$  \hspace{1cm} (18)

The general solution of equation (18) with (19) is

$$\xi(T) = C_1 \sqrt{S_0 + \gamma T} J_\nu \left(\frac{S_0 + \gamma T}{\gamma}\right) + C_2 \sqrt{S_0 + \gamma T} \nu J_{\nu-1} \left(\frac{S_0 + \gamma T}{\gamma}\right),$$  \hspace{1cm} (20)

where $J_\nu$ and $Y_{\nu-1}$ are the Bessel functions of first and second kind of order $\nu$, and $C_1$, $C_2$ are constants determined by the initial conditions. Therefore, the solution of equation (16) is

$$Z(T) = \left(1 + \frac{\gamma T}{S_0}\right)^{-\frac{1}{2}} \left[C_1 \sqrt{S_0 + \gamma T} J_\nu \left(\frac{S_0 + \gamma T}{\gamma}\right) + C_2 \sqrt{S_0 + \gamma T} \nu J_{\nu-1} \left(\frac{S_0 + \gamma T}{\gamma}\right)\right].$$  \hspace{1cm} (21)

If $Z(T = 0) = Z_0$ and $Z(T = 0) = 0$, the constants $C_1$ and $C_2$ are given by

$$C_1 = \frac{Z_0}{S_0^{\nu-1/2} \nu J_{\nu-1} \left(\frac{S_0}{\nu}\right) J_{\nu-1} \left(\frac{S_0}{\nu}\right) - \nu J_{\nu-1} \left(\frac{S_0}{\nu}\right) J_{\nu-1} \left(\frac{S_0}{\nu}\right)}$$

and

$$C_2 = \frac{Z_0}{S_0^{\nu-1/2} \nu J_{\nu-1} \left(\frac{S_0}{\nu}\right) J_{\nu-1} \left(\frac{S_0}{\nu}\right) - \nu J_{\nu-1} \left(\frac{S_0}{\nu}\right) J_{\nu-1} \left(\frac{S_0}{\nu}\right)}.$$  \hspace{1cm} (22)

The sign of the function $I(T)$, for which we have $dI/dT = \frac{1}{2} \gamma (1 - 2\gamma)/(S_0 + \gamma T)^3$, provides information on the oscillating behaviour.
of the solution. Thus, three cases can be distinguished, separated by
the critical value for settling $\gamma_c = \frac{1}{2}$:

(i) $0 < \gamma < \gamma_c = \frac{1}{2}$ and $\frac{dl}{dT} > 0$. $I$ increases from its initial
value $I(T = 0) < 1$ and $\lim_{T \to +\infty} I = 1$. If $S_t > \frac{1}{2} \sqrt{1 - 2 \gamma}$, then
$I(T = 0) > 0$ and $I$ is positive at all times: the solution is always
pseudo-oscillating. The dust particle is always decoupled from
the gas as the size can only increase and the dust evolution follows
the large grain regime. This is of minor interest in the context of
growing grains. We therefore consider the interesting case $S_t < \frac{1}{2} \sqrt{1 - 2 \gamma}$, for which $I(T = 0) < 0$ and $I$ becomes positive for
$T > \frac{1}{2} \sqrt{1 - 2 \gamma}$: the solution transitions from a monotonic decay to
a pseudo-oscillating regime, indicating that particles decouple from
the gas.

(ii) $\gamma = \gamma_c = \frac{1}{2}$ and $\frac{dl}{dT} = 0$. In this limiting case, $I(T) = 1$
for all time. Phase lag due to damped oscillations is exactly coun-
terbalanced by the decrease of the drag caused by grain growth.

(iii) $\gamma > \gamma_c = \frac{1}{2}$ and $\frac{dl}{dT} < 0$. $I$ decreases from its initial
value $I(T = 0) > 1$ and $\lim_{T \to +\infty} I = 1$. Since $I$ is always greater than
1, the solution is pseudo-oscillating at a frequency larger than the
Keplerian frequency.

The envelope of the solution, which determines the damping of
the dust’s vertical motion, is given by the product of $(1 + \frac{T}{S_0})^{-\frac{1}{2}}$, \sqrt{S_0 + \gamma T}$ and the envelope of the Bessel functions. While not
transparent, it is qualitatively interpretable. The dust behaviour for
different values of $\gamma$ are shown in Fig. 2 for $S_0 = 10^{-2}$. We focus on
initially small grains ($S_0 \ll 1$) because they correspond to the grains
which originate in the interstellar medium and are involved in planet
formation. In the case of the slow growth regime ($\gamma < 1/2$), the
vertical dust motion is damped efficiently: particles settle to the mid-
plane of the disc before they have time to grow and decouple from
the gas. However, as grains decouple slowly from the gas as they
settle, drag becomes weaker. Thus, dust settling occurs faster than
for non-growing grains and the settling rate increases for increasing
values of $\gamma$. On the contrary, in the fast growth regime ($\gamma > 1/2$),
dust particles grow fast enough to decouple from the gas before they
feel the gas drag and their settling time-scale becomes much longer.
In this case, the settling time of the grain increases dramatically
with $\gamma$ since an asymptotic expansion of equation (21) for $\gamma \gg 1$

provides $T_{sett} = O(e^\gamma / \gamma)$. In the intermediate case ($\gamma = 1/2$), dust
particles grow in the same time-scale as they settle to the mid-plane
where they decouple from the gas. This corresponds to the most
efficient regime of settling.

Additionally, Fig. 3 shows the evolution of the total energy $E$
given by

$$E = \frac{1}{2} \left( \dot{Z}^2 + Z^2 \right) = E(T = 0) - \int_0^T \frac{Z^2}{S(T')} dT',$$

for different values of the growth parameter $\gamma$. Even small values of $\gamma$
(e.g. $5 \times 10^{-3}$ or $5 \times 10^{-2}$ which correspond to real protoplanetary
disks) provide a dissipation which is more efficient than for the case
without any growth. The most efficient dissipation corresponds to
the most efficient settling obtained for $\gamma = 1/2$. Increasing again
the value of $\gamma$ leads to a less efficient dissipation process. In the
limit of large values of $\gamma$, the particles decouple so quickly from
the gas that the dissipation is even less efficient than for the case
without any growth.

3.3 Other growth models

We can also integrate the vertical motion of the grains for several
growth models: specifically power laws with $y_g = 1$, $-0.5$, 0.5
and growth rate given by the function $f$ of equation (13). For the
exponential growth rate model ($y_g = 1$), we derive analytically the evolution of the dimensionless vertical coordinate, which is given by

$$Z(T) = \left[ B_1 e^{\frac{z}{2}} \left( \gamma_S e^{\gamma_T} \right) + B_2 e^{\frac{z}{2}} \left( \gamma_S e^{\gamma_T} \right) \right] M \left( -\frac{1}{2}, \frac{1}{2}, \frac{e^{\gamma_T}}{\gamma_S} \right),$$

where $i^2 = -1$, $B_{1,2}$ are constants which are determined by the
initial conditions, and $M(a, b, z)$ is the M-Kummer confluent hy-
pergeometric function of indices $a$ and $b$ with respect to $z$.

For the other growth models, we did not manage to derive the
evolution analytically and therefore we must integrate the equations
numerically.

Fig. 4 shows the vertical behaviour of the particle with
$\gamma = 5 \times 10^{-2}$ (similar plots with $\gamma = 0.5$ and $\gamma = 5$ are shown in
Appendix B).
and $\gamma$ growth models is very similar. In particular, for $S > f$, the linear growth provides a good approximation of the function of small values of $\gamma$. Moreover, the exponential growth provides a good approximation of the function for the migration and the vertical settling process. The parameter space is divided in three regions as shown in Fig. 5: $\gamma < \eta_0$ (region 1), $\eta_0 < \gamma < 1/2$ (region 2) and $\gamma > 1/2$ (region 3), noting that $O(\eta_0) < 1/2$ for real discs. In each of these regions, the efficiency of the vertical (respectively, radial) motion is represented by the brightness of the top (respectively, bottom) colour bar. Importantly, this plot provides an indication of the relative efficiencies of the migration and settling processes, all the other parameters being fixed. It does not, however, predict the grains final state (decoupling at a finite radius, pile-up or accretion on to the star) but support the hypothesis of the decoupling between the radial and the vertical motions.

Efficiency of the vertical settling's efficiency in protoplanetary discs hold whatever the growth model considered.

4 COMBINING THE RADIAL AND THE VERTICAL MOTION

In the studies performed in Papers I, II and in this paper, we found two interesting values of the growth rate $\gamma$: $\gamma = \eta_0$ (giving $\Lambda = 1$) and $\gamma = 1/2$, corresponding, respectively, to the optimal values of $\gamma$ for the migration and the vertical settling process. The parameter space can therefore be divided in three regions as shown in Fig. 5: $\gamma < \eta_0$ (region 1), $\eta_0 < \gamma < 1/2$ (region 2) and $\gamma > 1/2$ (region 3), noting that $O(\eta_0) < 1/2$ for real discs. In each of these regions, the trajectories in the $(R, Z)$ plane of dust grains starting at $(R = 1, Z = 0.1)$ after a time $T = 240$ (thick lines) and $628$ (thin lines) with $S_0 = 10^{-3}$, $\eta_0 = 10^{-2}$, $p = 3/2$, $q = 3/4$, $n = 1$ and $\gamma = 10^{-4}, 10^{-3}, 5 \times 10^{-2}, 1/2, 10, 10^2$ (from top to bottom). We find that the most efficient value of $\gamma$ to reach $R_1 = 0.01$ is $\gamma_{c,m} = 0.050$, which corresponds to a time $T_1 = 240$.

In region 1 of Fig. 5, particles with small growth rates ($\gamma < \gamma_{c,m}$) settle to the mid-plane and then migrate towards the central star. Growth is not efficient enough to make the particles decouple from the gas before they reach the mid-plane and then migrate towards the central star. The migration efficiency is optimal for $\gamma = \gamma_{c,m}$. In region 2 of Fig. 5, grains with intermediate growth rates ($\gamma_{c,m} < \gamma < \gamma_{c,s} = 1/2$) grow as they settle to the mid-plane, radially migrate, but they decouple from the gas before reaching the central star and therefore experience an extremely slow migration motion. When $\gamma = \gamma_{c,s} = 1/2$ (the border of regions 2 and 3 of Fig. 5), the growth is optimal and particles decouple from the gas just as they reach the mid-plane.
Thus, particles migrate slightly while efficiently settling to the mid-plane (the envelope of vertical oscillations decreases very quickly). In region 3 of Fig. 5, the larger growth rates ($\gamma > \gamma_{c,s} = 1/2$) ensure that particles grow very efficiently and rapidly decouple from the gas. They do not settle to the mid-plane (as there is no gas damping once they decouple from the gas phase) and they experience a very small migration motion. In all cases, the vertical motion occurs much faster than the radial motion and the predictions done assuming that both motions are decoupled hold.

To pedagogically illustrate the effect of the linear growth rate discussed in Section 3.2 on the resulting dust distribution in protoplanetary discs, we also run simple simulations with the 3D two-phase code described in Barrière-Fouchet et al. (2005) with an initial setup similar to the one described in Laibe et al. (2008). We start with a uniform grain size $s_0 = 10 \mu$m (which corresponds to $s_0 = 10^{-3}$ at 50 au) in a disc where $\eta_0 = 10^{-2}$ at 5 au. The different evolutionary regimes predicted by the constant growth rate model and summarized in Fig. 5 are seen in the radial dust distribution in edge-on views of the disc shown in Fig. 7. For $\gamma = 10^{-4}$, particles experience only weak vertical settling which is characteristic of small grains. Their migration rate is also slow and thus they remain radially extended throughout the disc. For $\gamma = 10^{-2}$, both the vertical settling and the radial migration are very efficient. The particles close to the inner disc edge are rapidly accreted. However, for particles far from the inner edge, the pile-up is efficient enough to strongly retard the inward motion. For $\gamma = 1/2$, particles settle very efficiently to the disc mid-plane (minimum disc thickness). The less efficient migration also provides a larger disc. Grains which are not near the disc inner edge experience a slow migration regime and are not depleted. For $\gamma > 1/2$, growth occurs very rapidly: grains decouple from the gas in a fraction of an orbit and effectively remain on fixed Keplerian orbits and hence are distributed over the entire disc.

These different dust behaviours can also be illustrated by using the Lagrangian property of the SPH formalism and plotting trajectories of SPH dust particles for different values of $\gamma$ in the $rz$ plane (see Fig. 8). For $\gamma = 10^{-2}$, we see the particles fall to the mid-plane and migrate radially. When $\gamma = \frac{1}{2}$, the vertical settling is very efficient, but the migration is not and the values of $p$ and $q$ cause the dust to pile up radially. When $\gamma > \frac{1}{2}$, the migration is completely inefficient for the grains to reach the inner discs regions. When $\gamma = 10$, particles rapidly decouple from the gas and remain on inclined elliptical Keplerian orbits and can be seen oscillating about the disc mid-plane.

We also plot the dust size distribution obtained after approximately $10^5$ yr in Fig. 9. With our initial choice of $(p, q) = (\frac{1}{2}, \frac{1}{2})$ this ensures that $-p + q + \frac{1}{2} < 0$ and thus grains remain in the disc. Note however that the SPH disc is truncated at $r_{\text{in}} = 20$ au for reasons of computational efficiency. Thus, grains can be lost from the simulation if the time taken to reach $r_{\text{in}}$ is smaller than the simulation duration. For $\gamma = 10^{-4}$, particles close to the inner edge are lost, whereas for $\gamma = 10^{-2}$ the grains pile-up in the inner disc regions, staying beyond $\sim 25$ au. For the largest values of $\gamma$, particles decouple very quickly from the gas and remain distributed throughout the disc. The thickness of the size distribution corresponds to the dependency of $s_{\text{eq}}$ with respect to $z$ due to the vertical density profile. This is smallest for $\gamma = \gamma_{c,s} = 1/2$, for which vertical settling is most efficient and the dust disc is thinnest. As a conclusion, we find that the assumption of decoupling the radial and the vertical motion of the grain is verified both in our direct integration of the equations of motion (see Fig. 6) and in our SPH simulations (see Fig. 8).

5 CONCLUSIONS AND PERSPECTIVES

In this paper, we have studied the vertical settling of growing dust grains in protoplanetary discs, using different rates for the grain growth and integrating the equations of evolution both analytically and numerically. The main results of the study are as follows.

(i) The vertical motion of growing dust grains is governed by the value of the dimensionless parameter which represents the relative efficiency between the growth and the drag, which we denote by $\gamma$.  

![Figure 7](image_url)  

Figure 7. Radial grain size distribution obtained with our SPH code after $10^2$ yr for $\gamma = 10^{-4}$, $10^{-2}$, $1/2$ and 10. Dark blue: gas. Light blue: dust. Thinner disc distributions are obtained when the ratio between the growth time-scale is the same as the optimal settling time-scale ($\gamma = 1/2$).
In protoplanetary discs, $\gamma$ is of the same order as the initial dust-to-gas ratio of the disc $\epsilon_0$, which is of order $10^{-2}$. This implies that the growth is not too efficient (the effective $\gamma$ being much smaller than the critical value of 1/2) enabling particles to settle towards the disc mid-plane where they concentrate.

(ii) All the growth models we have tested give essentially the same behaviour as the linear growth model. We therefore suggest that the results of this study are generalizable and that the solution of this study are generalizable and that the solution

(iii) Simultaneously integrating both the radial and the vertical motion of the particles shows that the vertical settling of the particles occurs much faster than the radial drift of the particles, justifying the assumption of separating the radial drift and the vertical settling. This is a standard and well-known result for non-growing grains (see e.g. Garaud et al. 2004), we have shown that it also holds for growing grains.

(iv) Combining the results for the radial drift with the study of the vertical settling of dust grains, we distinguish three major regimes for growing grains: $\gamma < \eta_0$, $\eta_0 < \gamma < 1/2$, $1/2 < \gamma$, the first two being the most relevant for the context of planet formation. Initially, small grains grow as they settle to the mid-plane, the settling motion being faster than for non-growing grains. Varying $\gamma$ results in distinct profiles for the grain size distribution as well as their spatial distributions.

Importantly, dust concentration of growing grains in the disc mid-plane has been proven to occur when the disc is laminar. If not, turbulent fluctuations from the gas may spread the dust particles out of the disc mid-plane. This vertical stirring is widely supposed to prevent grains to concentrate in the disc mid-plane and form planet by gravitational instability for non-growing grains. This issue will be addressed in the case of growing dust grains in a forthcoming paper.

ACKNOWLEDGEMENTS

This research was partially supported by the Programme National de Physique Stellaire and the Programme National de Planétologie of CNRS/INSU, France and the Agence Nationale de la Recherche (ANR) of France through contract ANR-07-BLAN-0221. STM acknowledges the support of a Swinburne Special Studies Programme. GL is grateful to the Australian Research Council for funding via Discovery project grant DP1094585, and acknowledges funding from the European Research Council for the FP7 ERC advanced grant project ECOGAL. JFG’s research was conducted within the Lyon Institute of Origins under grant ANR-10-LABX-66. M. Hutchinson is acknowledged for his thorough relecture of this series of papers.

APPENDIX B: SETTLING WITH DIFFERENT GROWTH MODELS

Figs B1 and B2 show the vertical evolution of particles for different growth models. No significant differences are found between the models.

Figure B1. Vertical motion of a growing dust particle starting at $Z_0 = 1$ with $S_0 = 10^{-2}$ and $\gamma = 1/2$ for different growth models. No significant differences are found between the different models.

Figure B2. Vertical motion of a growing dust particle starting at $Z_0 = 1$ with $S_0 = 10^{-2}$ and $\gamma = 5$ for different growth models. No significant differences are found between the different models.
