ABSTRACT

M-dwarfs are emerging in the literature as promising targets for detecting low-mass, Earth-like planets. An important step in this process is to determine the stellar parameters of the M-dwarf host star as accurately as possible. Different well-tested stellar model atmosphere simulations from different groups are widely applied to undertake this task. This paper provides a comparison of different model atmosphere families to allow a better estimate of systematic errors on host-star stellar parameter introduced by the use of one specific model atmosphere family only. We present a comparison of the ATLAS9, MARCS, PHOENIX and DRIFT-PHOENIX model atmosphere families including the M-dwarf parameter space (T_{eff} = 2500–4000 K, $\log(g)$ = 3.0–5.0, [M/H] = -2.5 to 0.5). We examine the differences in the (T_{gas}, p_{gas})-structures, in synthetic photometric fluxes and in colour indices. Model atmospheres results for higher $\log(g)$ deviate considerably less between different models families than those for lower $\log(g)$ for all T_{eff} = 2500–4000 K examined. We compiled the broad-band synthetic photometric fluxes for all available model atmospheres (incl. M-dwarfs and brown dwarfs) for the UKIRT WFCAM *ZYJHK*, 2MASS *JHKs* and Johnson *UBVRI* filters, and calculated related colour indices. Synthetic colours in the IR wavelengths diverge by no more than 0.15 dex amongst all model families. For all spectral bands considered, model discrepancies in colour diminish for higher T_{eff} atmosphere simulations. We notice differences in synthetic colours between all model families and observed example data (including Kepler 42 and GJ1214).

Key words: stars: atmospheres – brown dwarfs – stars: late-type.

1 INTRODUCTION

Ever since the discoveries of the first extrasolar planets (Wolszczan & Frail 1992; Mayor & Queloz 1995; Charbonneau et al. 2000), exoplanetary science has been one of the hot topics in astronomy in the past two decades. High-precision instruments and missions such as HARPS (Mayor et al. 2003), *CoRoT* (Auvergne et al. 2009), *Kepler* (Batalha et al. 2013) and the future PLATO[1]-mission have allowed the number of known exoplanets to grow rapidly. Up to date, the Exoplanet Encyclopaedia (exoplanet.eu) lists a total of 1822 planets in 1137 planetary systems. Better instruments and enhanced observational techniques are pushing the boundaries of detectable planets down to the Super-Earth group. In order to achieve this goal, target host stars decrease in mass. M-dwarfs, and also brown dwarfs (Triaud et al. 2013), are suggested as they have smaller radii, masses and are less luminous, presenting opportunities for detecting smaller planets orbiting around them, possibly even within their respective habitable zones (HZs). The solar neighbourhood has been photometrically, spectroscop-

ically and astrometrically studied by the RECONS team (Henry et al. 2006) in order to understand the distribution of stellar types nearby. Their latest finding (Dieterich et al. 2012) indicate that M- and later type stars account for 60–70 per cent of the stellar population within 10 pc of the Sun. The fact that they are so numerous additionally increases the chances of planet detections, making M-dwarfs and brown dwarfs even more desirable survey targets. On the other hand, habitability on planets around these stars will be limited by their magnetic activity (see Vidotto et al. 2013, for details).

The Exoplanet Encyclopaedia list a total of 36 confirmed planets around M-dwarfs with about 2/3 of them with masses under 0.2 M_J. There are no detections of planets around brown dwarfs so far. Data from *Kepler* suggests that early M-dwarfs have an occurrence rate of, on average, $0.90^{+0.04}_{-0.03}$ planets per star with planet parameters in range 0.5–4 R_{Earth} and P < 50 d (Dressing & Charbonneau 2013). Monet et al. (2013) combine radial velocity and adaptive optics direct imaging observations for a sample of 111 M stars. They report that 6.5 ± 3.0 per cent of the M-dwarfs host a gas giant with mass between 1–13 M_J and semimajor axes of less than 20 au, corresponding to 0.083 ± 0.019 planets per star in that parameter space. These results suggest that planets around M-dwarfs are abundant, motivating future studies to characterize them in detail (e.g. Önehag

et al. 2012; Mann et al. 2014; Newton et al. 2014; Rajpurohit et al. 2014).

The evaluation of planet parameters is tightly correlated with the host star's parameters (e.g. Torres et al. 2012; Griffith 2014). Therefore our knowledge about extrasolar planets is limited by how well we can characterize the host stars. The challenge of determining fundamental stellar parameters is not new (see Rojas-Ayala et al. 2013) and not restricted to planetary host stars (e.g. Casagrande et al. 2014 and references therein). Burrows, Heng & Nampaisarn (2011) generate evolutionary tracks for brown dwarfs and very low mass stars for different atmospheric metallicities with and without clouds. By comparing observational data to these tracks, their study demonstrates a variety of plausible stellar radii, and narrowing down this range for a given mass depends on precise estimates of stellar age and metallicity. Lee, Heng & Irwin (2013) use inverse modelling of directly-imaged data for HR 8799B. Their results indicate that reasonable fits to the data can be obtained for both cloudy and cloud-free atmospheres but with different values for metallicities and element abundances. Such studies indicate the difficulty of inferring precise values for stellar parameters based on atmospheric models. Both, variations in underlying physical assumptions between models and different parameter values, within the same model can lead to a spread in estimates for stellar mass and radii. It is therefore important to be aware of the limitations of model atmospheres and how they compare to each other.

This paper focuses on the comparison of different model atmosphere families with some focus on the M-dwarf parameter space: effective temperature $T_{eff} = 4000$–2500 K, surface gravity spans $\log(g)$=3.0–5 (included young M-dwarfs, $\log(g)$<4.0, and Brown Dwarfs, $\log(g) = 5.0$), and metallicity [M/H]=-2.5to0.5 (Appendix A). Not all parameter combinations are available for all model families. Section 2 gives a brief overview of the atmosphere models used in this study. In Section 3, we explore the similarities and differences in the atmospheric structure of the model families. In Section 4, we present the results for the synthetic photometry comparisons. Section 5 contains our discussion.

2 ATMOSPHERE MODEL FAMILIES IN COMPARISON

The following model atmosphere families are included in the comparison study presented in this paper:

(i) ATLAS9[2] (Kurucz 1970; Castelli & Kurucz 2004),
(ii) MARCS[3] (Gustafsson et al. 2008),
(iii) (cloud-free) PHOENIX-ACES-AGSS-COND-2011[4], version 16.01.00B (hereafter PHOENIX) (Husser et al. 2013),
(iv) DRIFT-PHOENIX (Dehn 2007; Helling et al. 2008c; Witte, Helling & Hauschildt 2009; Witte et al. 2011).

All models assume local thermodynamic equilibrium, hydrostatic and chemical equilibrium and obey radiative and convective flux conservation. They model a homogeneous, 1D oxygen-rich atmosphere in plane-parallel geometry. PHOENIX models were available in spherical symmetry.

The grid of ATLAS models utilized spans the following range of stellar parameter: $T_{eff} = 3500$–4000 K, $\log(g) = 3.0$–5.0, [M/H] = 0.5to $- 2.5$. All ATLAS models were calculated with the convection option switched on but with the overshooting option switched off. The mixing length parameter $\alpha = l/H_p = 1.25$, ($H_p = p/(g\rho)$, H_p – local pressure scaleheight, p – local gas pressure, ρ – local gas density, g – local gravitational acceleration, where $dp/dr = g\rho$), the microturbulence velocity $v_{turb} = 2.0$ km s^{-1}, and solar element abundances from Grevesse & Sauval 1998 are used in all ATLAS models considered here.

The MARCS models used span a grid of $T_{eff} = 2500$ K–4000 K, $\log(g) = 3.0$–5.5, [M/H] = 0.5to $- 2.5$. For all MARCS models, $v_{turb} = 2$ km s^{-1}, mixing length parameter with $l/H_p = 1.5$ and solar element abundances (Grevesse, Asplund & Sauval 2007).

The PHOENIX models considered are for $T_{eff} = 2500$ K–4000 K, $\log(g) = 3.0$–5.5, [M/H] = 0.0 and α-element abundance of [α/M] = 0.0.

Values for the mixing length parameter $l/H_p \sim 3.0$–1.8 depending on the stellar parameters as depicted in fig. 2 in Husser et al. (2013). Figs 1–4 provide the detailed information regarding the model atmospheres compared. The microturbulence velocities $v_{turb} < 1.5$ km s^{-1} according to fig. 3 in Husser et al. (2013). The element abundances are solar (Asplund et al. 2009).

The DRIFT-PHOENIX models are aimed specifically at late-type stars (M-dwarfs, brown dwarfs) and giant planet atmospheres as they also model dust cloud formation. The DRIFT module deals with dust treatment, calculating a consistent cloud structure and passing it to the main radiative transfer code (PHOENIX). The subset of models used is for the solar metallicity models with 2500 K < T_{eff} < 3000 K and 3.0 < $\log(g)$ < 5.5. Mixing length is set to 2.0 scaleheights and microturbulence velocity is 2.0 km s^{-1}. Solar elements abundances are those from (Grevesse et al. 2007)

The different model atmosphere families of models cover different parts of the M-dwarf regime, with ATLAS barely touching early-type M stars, DRIFT-PHOENIX covering the late end of this spectral type and MARCS and PHOENIX spanning the entire M-dwarf range. The different sets of element abundances applied for different model families are summarized in Table 1. All non-solar metallicities are derived from scaled solar values. More detailed information about the models, e.g. regarding the used opacity sources, are provided in the discussion Section 5.1.

The model atmospheres under investigation do not contain one M-dwarf parameter set that is common to all of them. Therefore, we compare subsets of model families: the ATLAS+MARCS models for $T_{eff} = 3500$ K and $T_{eff} = 4000$ K and varying $\log(g)$ and [M/H] values, ATLAS+MARCS+PHOENIX for $T_{eff} = 3500$ K and $T_{eff} = 4000$ K, [M/H] = 0.0 and varying $\log(g)$, as well as the MARCS+DRIFT-PHOENIX, MARCS+PHOENIX and PHOENIX+DRIFT-PHOENIX models for solar metallicity and varying T_{eff} and $\log(g)$ values. A total of 141 models were examined. Appendix A summarize the parameter values of all models used.

3 COMPARING THE ATMOSPHERE STRUCTURES

Model atmosphere simulations provide the numerical solution to energy transfer by radiation and convection, hydrostatic equilibrium and gas-phase equilibrium chemistry. The radiative energy transfer is likely to carry inconsistencies between the model families as it depends on element abundances, gas-phase number
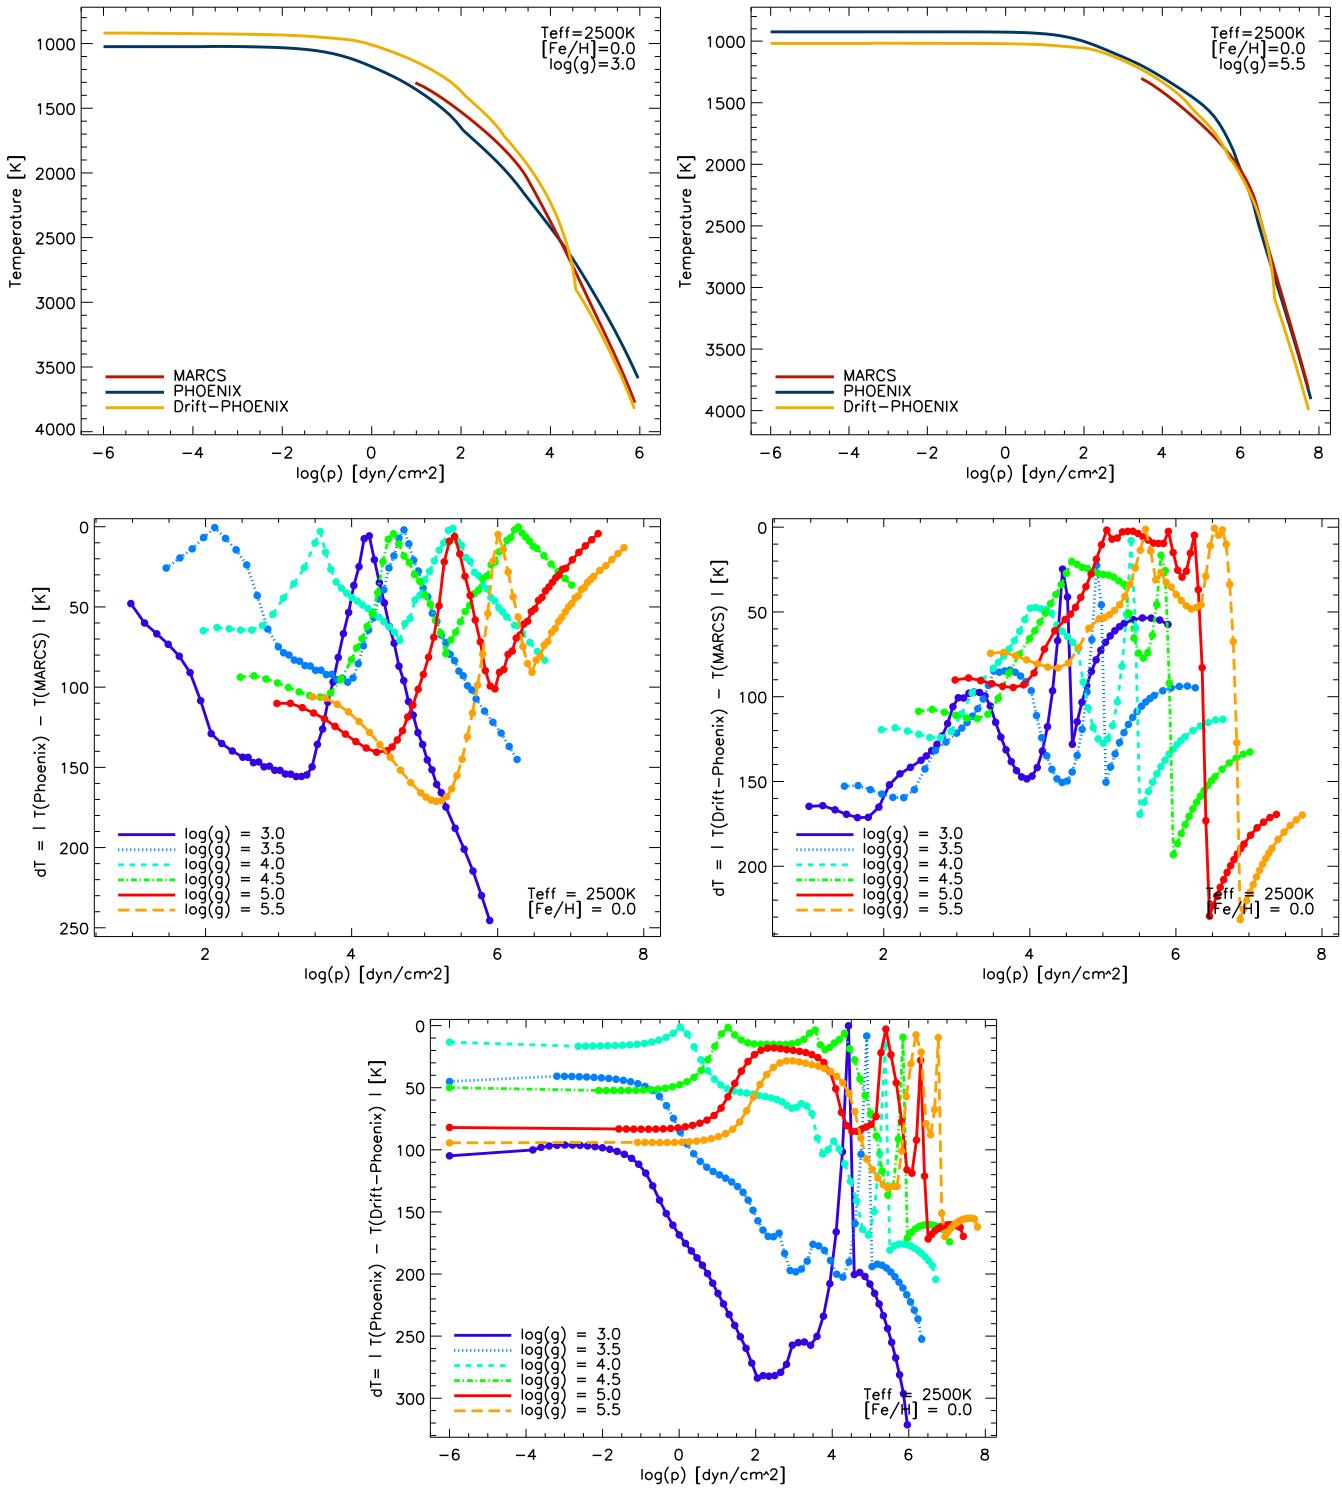

Figure 1. Top row: local gas temperature–pressure structures for $T_{\mathrm{eff}} = 2500$ K ($\log(g) = 3.0$: top left; $\log(g) = 5.5$: top right) for MARCS, PHOENIX and DRIFT-PHOENIX. Middle row: left – residual temperature values $\mathrm{d}T_{\mathrm{gas}}$ between PHOENIX and MARCS; right – $\mathrm{d}T_{\mathrm{gas}}$ between DRIFT-PHOENIX and MARCS. Bottom row: $\mathrm{d}T_{\mathrm{gas}}$ between DRIFT-PHOENIX and PHOENIX model atmosphere results. Mixing length parameter: PHOENIX–$l/H_{\mathrm{p}} = 2.79$ for $\log(g) = 3.0$ and $l/H_{\mathrm{p}} = 3.5$ for $\log(g) = 5.5$; MARCS–$l/H_{\mathrm{p}} = 1.5$ for all models; DRIFT-PHOENIX–$l/H_{\mathrm{p}} = 2.0$ for all models.

densities and line lists for those species taken into account as opacity sources in each of the atmosphere models. Other differences between model atmosphere results from different codes are caused by different numerical schemes used, difference in convergence criteria applied, maybe by differences in the machines where the code is run, or also by different hidden parameters like e.g. the outer

integration boundary. This paper can only present the effect of the sum of all these factors on the results from different model families and showcase how and if the results differ. Without a dedicated benchmark study, like e.g. Helling et al. (2008a), a more detailed assessment of the differences between the model families is not possible.
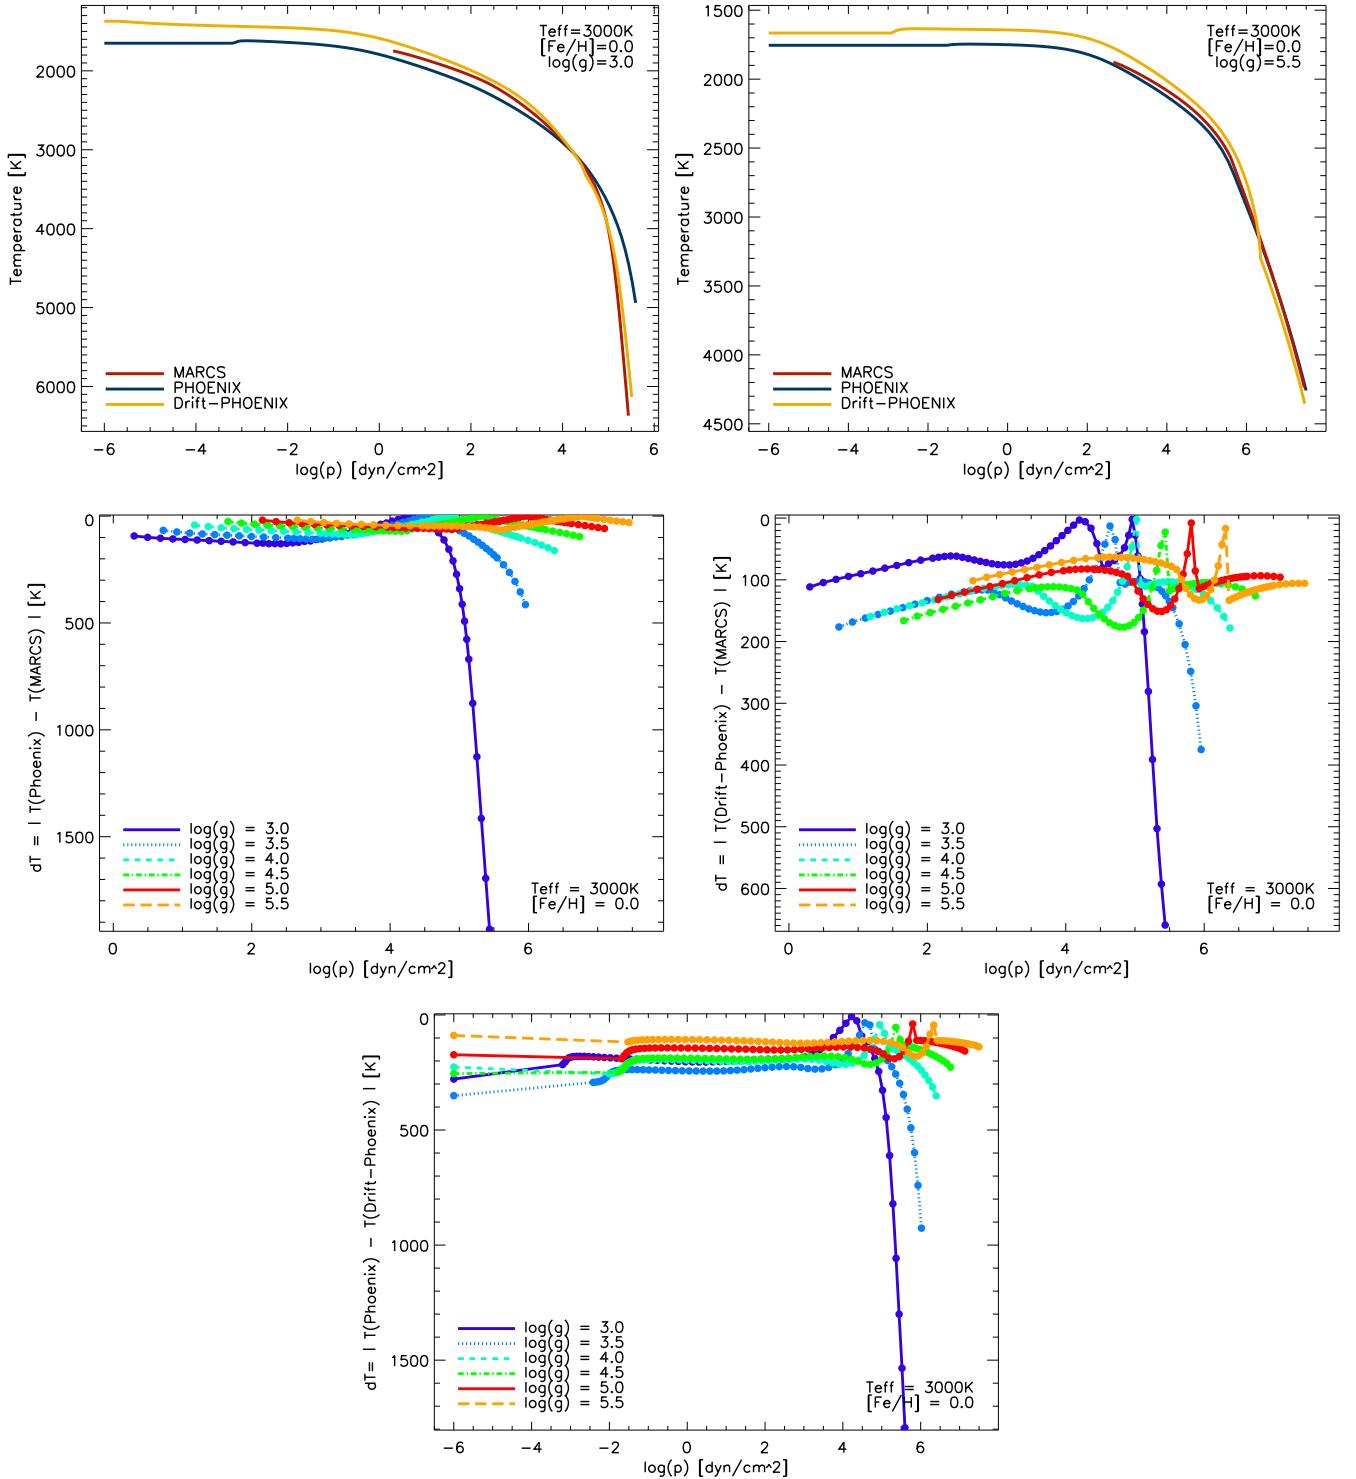

Figure 2. Top row: local gas temperature–pressure structures for $T_{\rm eff} = 3000$ K ($\log(g) = 3.0$: top left; $\log(g) = 5.5$: top right) for MARCS, PHOENIX and DRIFT-PHOENIX. Middle row: left – residual temperature values $dT_{\rm gas}$ between PHOENIX and MARCS; right – $dT_{\rm gas}$ between DRIFT-PHOENIX and MARCS. Bottom row: $dT_{\rm gas}$ between DRIFT-PHOENIX and PHOENIX model atmosphere results. Mixing length parameter: PHOENIX–$l/H_{\rm p} = 2.3$ for $\log(g) = 3.0$ and $l/H_{\rm p} = 3.25$ for $\log(g) = 5.5$; MARCS–$l/H_{\rm p} = 1.5$ for all models; DRIFT-PHOENIX–$l/H_{\rm p} = 2.0$ for all models.

The local gas temperatures and gas pressures affect number densities of chemical species, which in turn affects opacities and, hence, result in differences in the emergent spectral energy distribution (SED). We therefore start our investigation by examining the local $(T_{\rm gas}, p_{\rm gas})$ structures of model atmospheres for a given set of $T_{\rm eff}$, $\log(g)$ and [M/H] values.

Figs 1–4 present the comparison of the $(T_{\rm gas}, p_{\rm gas})$-structures of MARCS, PHOENIX, DRIFT-PHOENIX and ATLAS[5] for solar metallicity

[5] The 'kink' in the ATLAS local temperature–pressure profile in Fig 3, top row, right-hand panel, is visible in other models with $T_{\rm eff} = 3000\,K$ and solar metallicity.
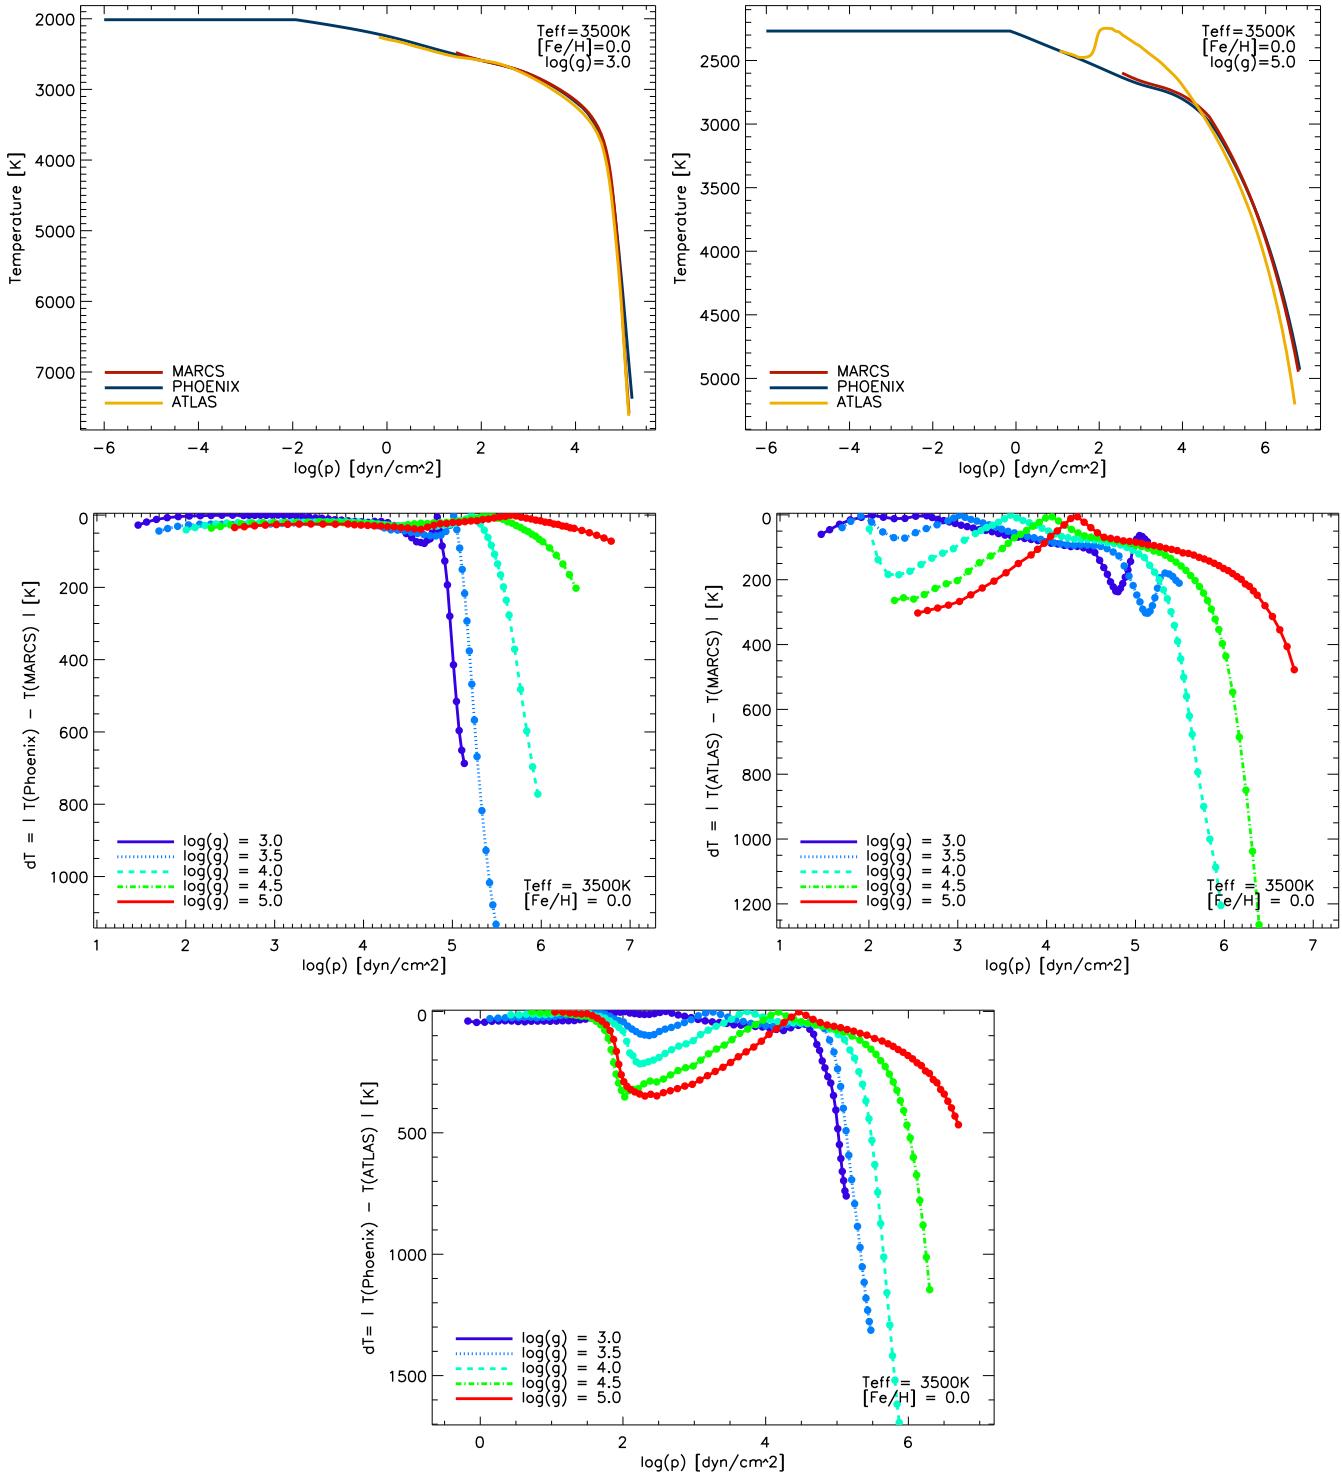

Figure 3. Top row: local gas temperature–pressure structures for $T_{eff} = 3500$ K ($\log(g) = 3.0$: top left; $\log(g) = 5.0$: top right) for MARCS, PHOENIX and ATLAS. Middle row: left – residual temperature values dT_{gas} between PHOENIX and MARCS; right – dT_{gas} between ATLAS and MARCS. Bottom row: dT_{gas} between PHOENIX and ATLAS model atmosphere results. Mixing length parameter: PHOENIX–$l/H_p = 1.99$ for $\log(g) = 3.0$ and $l/H_p = 2.39$ for $\log(g) = 5.0$; ATLAS–$l/H_p = 1.25$ for all models; MARCS–$l/H_p = 1.5$ for all models.

and $T_{eff} = 2500, 3000, 3500$ and 4000 K, respectively. We observe better agreement between MARCS, PHOENIX and DRIFT-PHOENIX for $T_{eff} = 2500$ K than for higher T_{eff} models. The 2500 K sets of models do not vary by more than 300 K (except for high-pressure values). For all effective temperatures ($T_{eff} = 2500$–

4000 K), the model atmospheres with higher surface gravity (brown dwarfs) agree better between different model families than those with lower surface gravity (giant gas planets, young brown dwarfs). Note these differences are hard to see in the top rows of Figs 1–4 due to the scale of the plots. For this reason, we
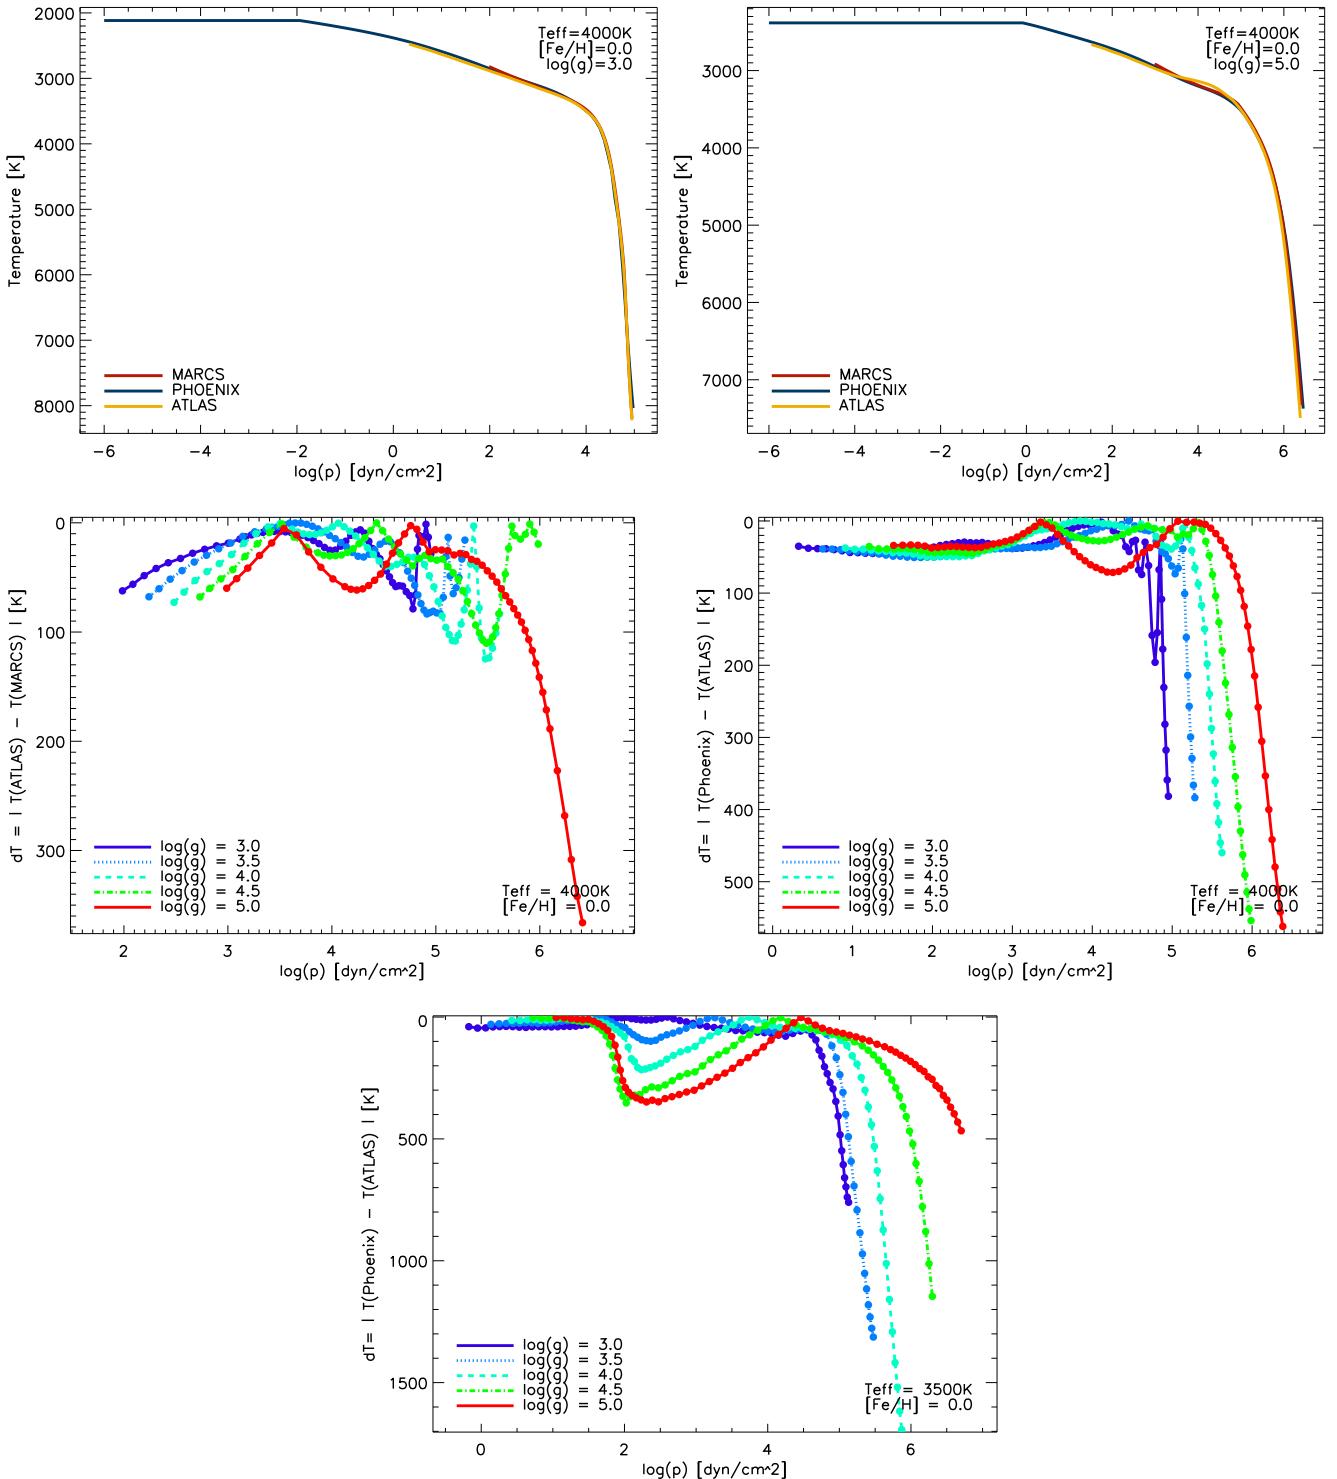

Figure 4. Top row: local gas temperature–pressure structures for $T_{\rm eff} = 4000$ K ($\log(g) = 3.0$: top left; $\log(g) = 5.0$: top right) for MARCS, PHOENIX and ATLAS. Middle row: left – residual temperature values $dT_{\rm gas}$ between PHOENIX and MARCS; right – $dT_{\rm gas}$ between ATLAS and MARCS. Bottom row: $dT_{\rm gas}$ between PHOENIX and ATLAS model atmosphere results. Mixing length parameter: PHOENIX–$l/H_{\rm p} = 1.82$ for $\log(g) = 3.0$ and $l/H_{\rm p} = 1.96$ for $\log(g) = 5.0$; ATLAS–$l/H_{\rm p} = 1.25$ for all models; MARCS–$l/H_{\rm p} = 1.5$ for all models.

provide plots of the calculated residuals in rows 2 and 3 of the figures.

We compare the hot ATLAS and MARCS models for $T_{\rm eff} = 3500$ K and $T_{\rm eff} = 4000$ K. While the $T_{\rm eff} = 3500$ K models compare better in the low-metallicity range $-1.5 < [{\rm M/H}] < -2.5$, the

$T_{\rm eff} = 4000$ K models display better agreement for higher metallicities $[{\rm M/H}] = +0.5$ and $[{\rm M/H}] = 0.0$. For both $T_{\rm eff}$, the biggest discrepancies lie within the $[{\rm M/H}] = -1.0$ models, with local gas temperature differences $dT_{\rm gas} > 1500$ K for the $T_{\rm eff} = 3500$ K and $dT_{\rm gas} > 1200$ K for the $T_{\rm eff} = 4000$ K case. All model families

diverge with increasing local pressure, i.e. deeper in the atmosphere, regardless of T_{eff}, $\log(g)$ or metallicity [M/H]. The detailed plots for $T_{eff} = 4000$ K, $\log(g) = 5.0$ can be found in Appendix B, Fig. B1.

In summary, we find that for the higher effective temperature values (3500 K, 4000 K) the ATLAS, PHOENIX and MARCS (T_{gas}, p_{gas})-structures diverge from each other with an average of $\sim$600 K in local temperature and in extreme cases well over 1000 K. The MARCS, PHOENIX and DRIFT-PHOENIX differ by an average of $\sim$300 K for 2500 K $< T_{eff} <$ 4000 K, with some extreme cases of over 1000 K. Agreement improves as the surface gravity increases.

4 COMPARING SYNTHETIC PHOTOMETRY

The (T_{gas}, p_{gas})-structure determines the emergent spectral energy distribution for stars. In order to compare the SEDs of the different model atmosphere families, we perform synthetic photometry for all models considered. We convolve the model SEDs to the (UKIDSS) UKIRT WFCAM *ZYHJK* (Hewett et al. 2006), 2MASS *JHKs* (Cohen, Wheaton & Megeath 2003) and Johnson *UBVRI* (Johnson 1965) filter systems, based on codes used in Sinclair, Helling & Greaves (2010). The wavelength ranges for these used filters are summarized in Table C1.

The convolved broad-band flux F_R is given by (Straizys 1996)

$$F_R(\lambda) = \frac{\int_{\lambda_1}^{\lambda_2} F(\lambda)R(\lambda)\mathrm{d}\lambda}{\int_{\lambda_1}^{\lambda_2} R(\lambda)\mathrm{d}\lambda}, \qquad (1)$$

where $R(\lambda)$ is the throughput function (only filter transmission for the optical (*UBVRI*) bands, but filter transmission plus detector throughput for 2MASS/UKIDSS); and λ_1 and λ_2 are the limits of the filter wavelength range. Zero-point calibration is performed using the *HST* spectrum of Vega (Bohlin & Gilliland 2004).

We proceed to calculate synthetic colour indices for each model atmosphere family. The colour indices are defines as

$$m_1 - m_2 = -2.5(\log(\frac{F_{R1}}{F_{R1,\mathrm{Vega}}}) + \log(\frac{F_{R2}}{F_{R2,\mathrm{Vega}}})). \qquad (2)$$

A complete set of the synthetic photometry results is provided in Appendix C. In the following, we compare the ratios between the synthetic broad-band fluxes for all pairs of corresponding models in each filter. The closer the value to 1.0, the more similar the model atmosphere results are.

4.1 Optical bands (Johnson *UBVRI* filters)

The broad-band fluxes of ATLAS and MARCS model atmospheres in the optical differ significantly more than those in the IR range. The flux ratios for $T_{eff} = 3500$ K are deviating from 1.0 significantly more (as high as $\sim$1.8) than those for $T_{eff} = 4000$ K (less than $\sim$1.3). The ATLAS models predict more flux than MARCS in the U band for metallicities above [M/H] $= -1.0$ and then drop to as low as about 20 per cent less flux for [M/H] > -1.0 for both effective temperatures. In the V band, the ATLAS model predict systematically higher fluxes than MARCS. Corresponding plots are provided in Figs B2 and B3.

4.2 IR bands

Figs 5 and 6 represent the UKIDSS photometric flux ratios for PHOENIX to MARCS and PHOENIX to DRIFT-PHOENIX. PHOENIX and MARCS display a good agreement in the range $T_{eff} = 3500$–4000 K. A possible explanation for the decreasing discrepancies in this T_{eff} range relative to $T_{eff} < 3000$ K is the lack of dust as effective temperature rises. Dust should not have an impact on the atmospheric structures in models with $T_{eff} >$ 3000 K (Witte et al. 2009).

For decreasing effective temperature, the PHOENIX models systematically predict more flux in the IR bands than the MARCS model atmospheres for higher $\log(g)$ values and less flux than MARCS for low $\log(g)$. The Y band is an exception to this trend, where, for $T_{eff} < 3500$ K all PHOENIX models predict less flux than MARCS with the flux ratio dropping as low as 0.7. Both model families do not include cloud formation in the model atmospheres considered here, hence, the differences in fluxes may point to differences in the molecular opacities (line lists and/or gas-phase chemistry data).

We compare the PHOENIX and DRIFT-PHOENIX model atmospheres (2500 K $\leq T_{eff} \leq$ 3000 K) in order to check if the difference in dust treatment is sufficient to explain differences in synthetic fluxes (Fig. 6). Differences between these two families are generally smaller than in comparisons with the MARCS model atmospheres. For the H and J bands, all PHOENIX atmosphere models predict less flux than DRIFT-PHOENIX. This result is unexpected as these bands are heavily affected by dust and the PHOENIX models are dust-free. Therefore, while still an important factor, the dust treatment alone cannot explain the observed trends in the comparison of the synthetic fluxes. All models produce very similar fluxes in the K band.
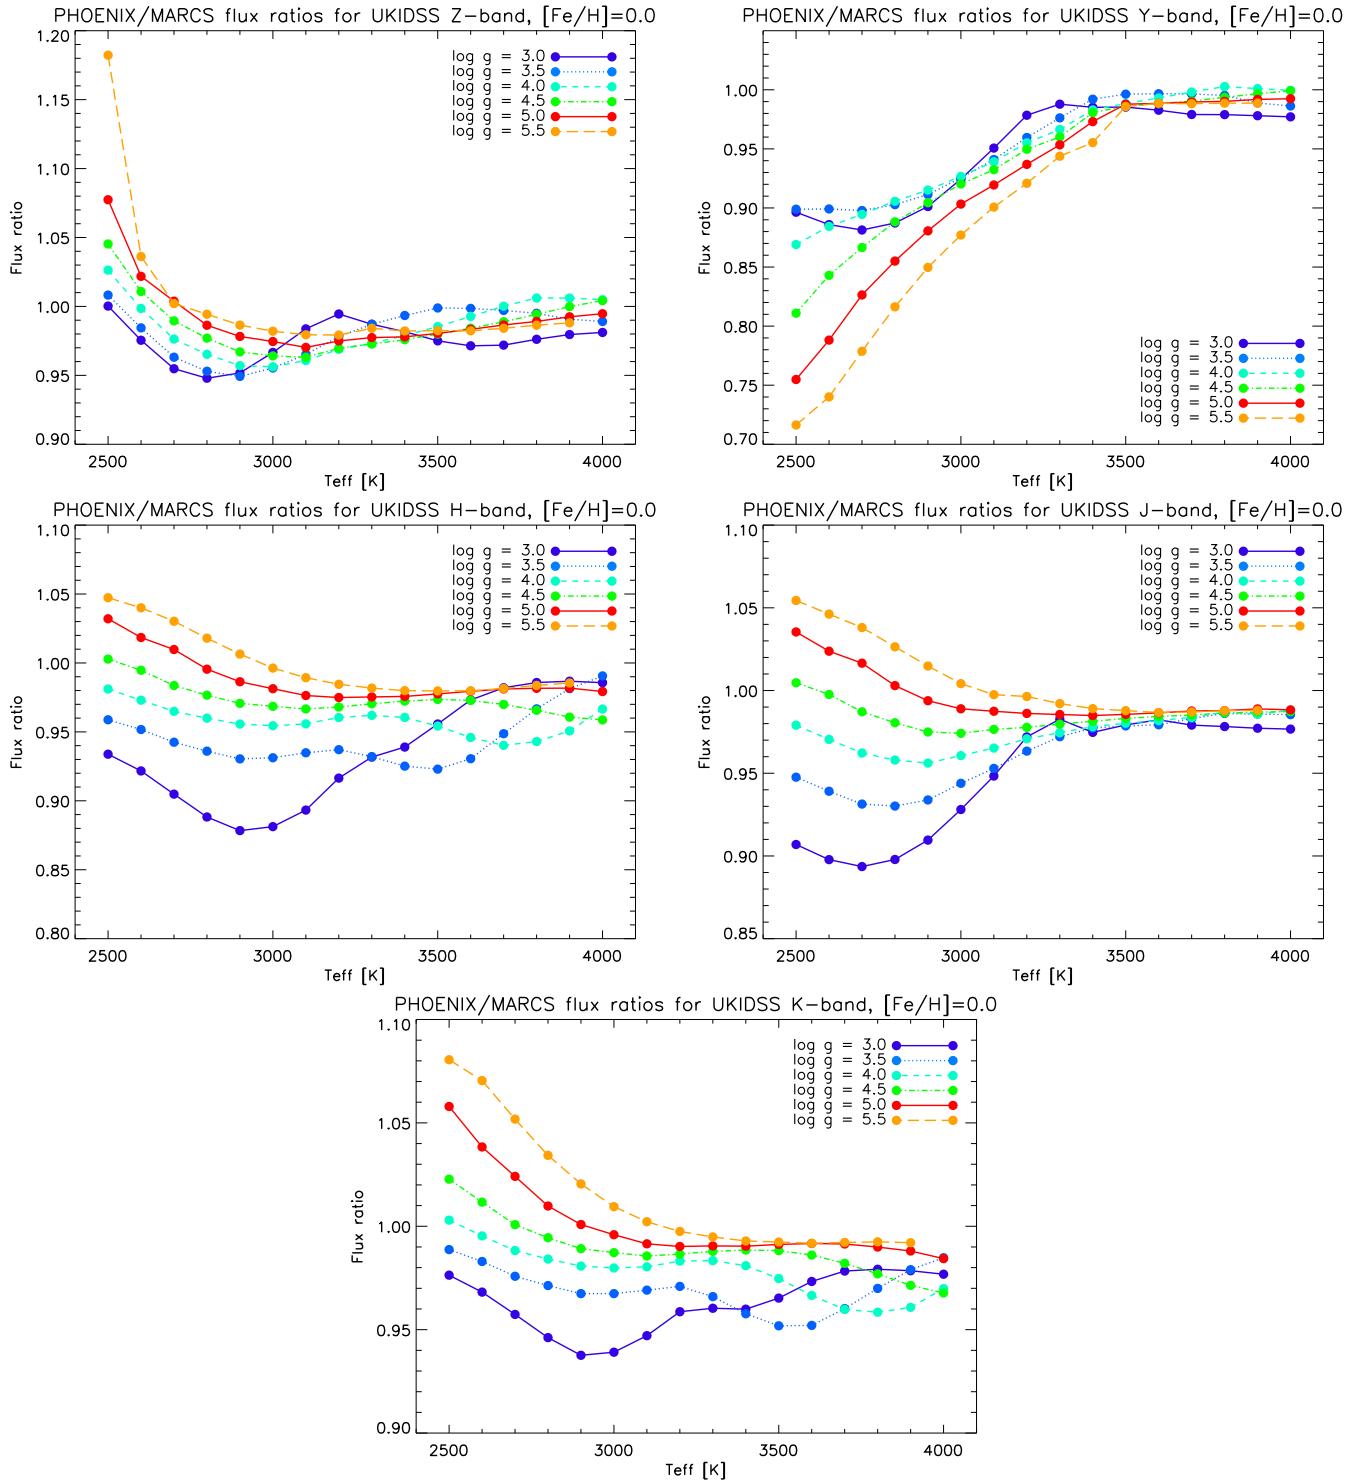

Figure 5. Convolved flux ratios for PHOENIX and MARCS atmosphere models for the UKIDSS filter system. Curves are colour coded with respect to log(*g*) value: orange – 5.5, red – 5.0, green – 4.5, cyan – 4.0, blue – 3.5, dark blue – 3.0. All models here are of solar metallicity.

For all bands, except in the *Z* band, the flux ratio is highest for the higher surface gravity values. This trend is reversed in the *Z* band, which also appears to vary the most with change in $T_{\rm eff}$.

We also present the colour indices calculated for each model atmosphere family considered here (Fig. 7 and Appendix C). All colours show considerable differences for model atmospheres $T_{\rm eff} < 3000$ K. Dust starts to form in small amounts at $T_{\rm eff} \approx 2700$ K

and the resulting element depletion of the gas-phase may contribute to the increasing differences with decreasing $T_{\rm eff}$ below 2700 K (Witte et al. 2009). In particular, the $B-V$ magnitudes differ by up to half a magnitude between the DRIFT-PHOENIX and MARCS models in the low temperature half of the plot. The ATLAS models appear to differ significantly from all other model families considered here.
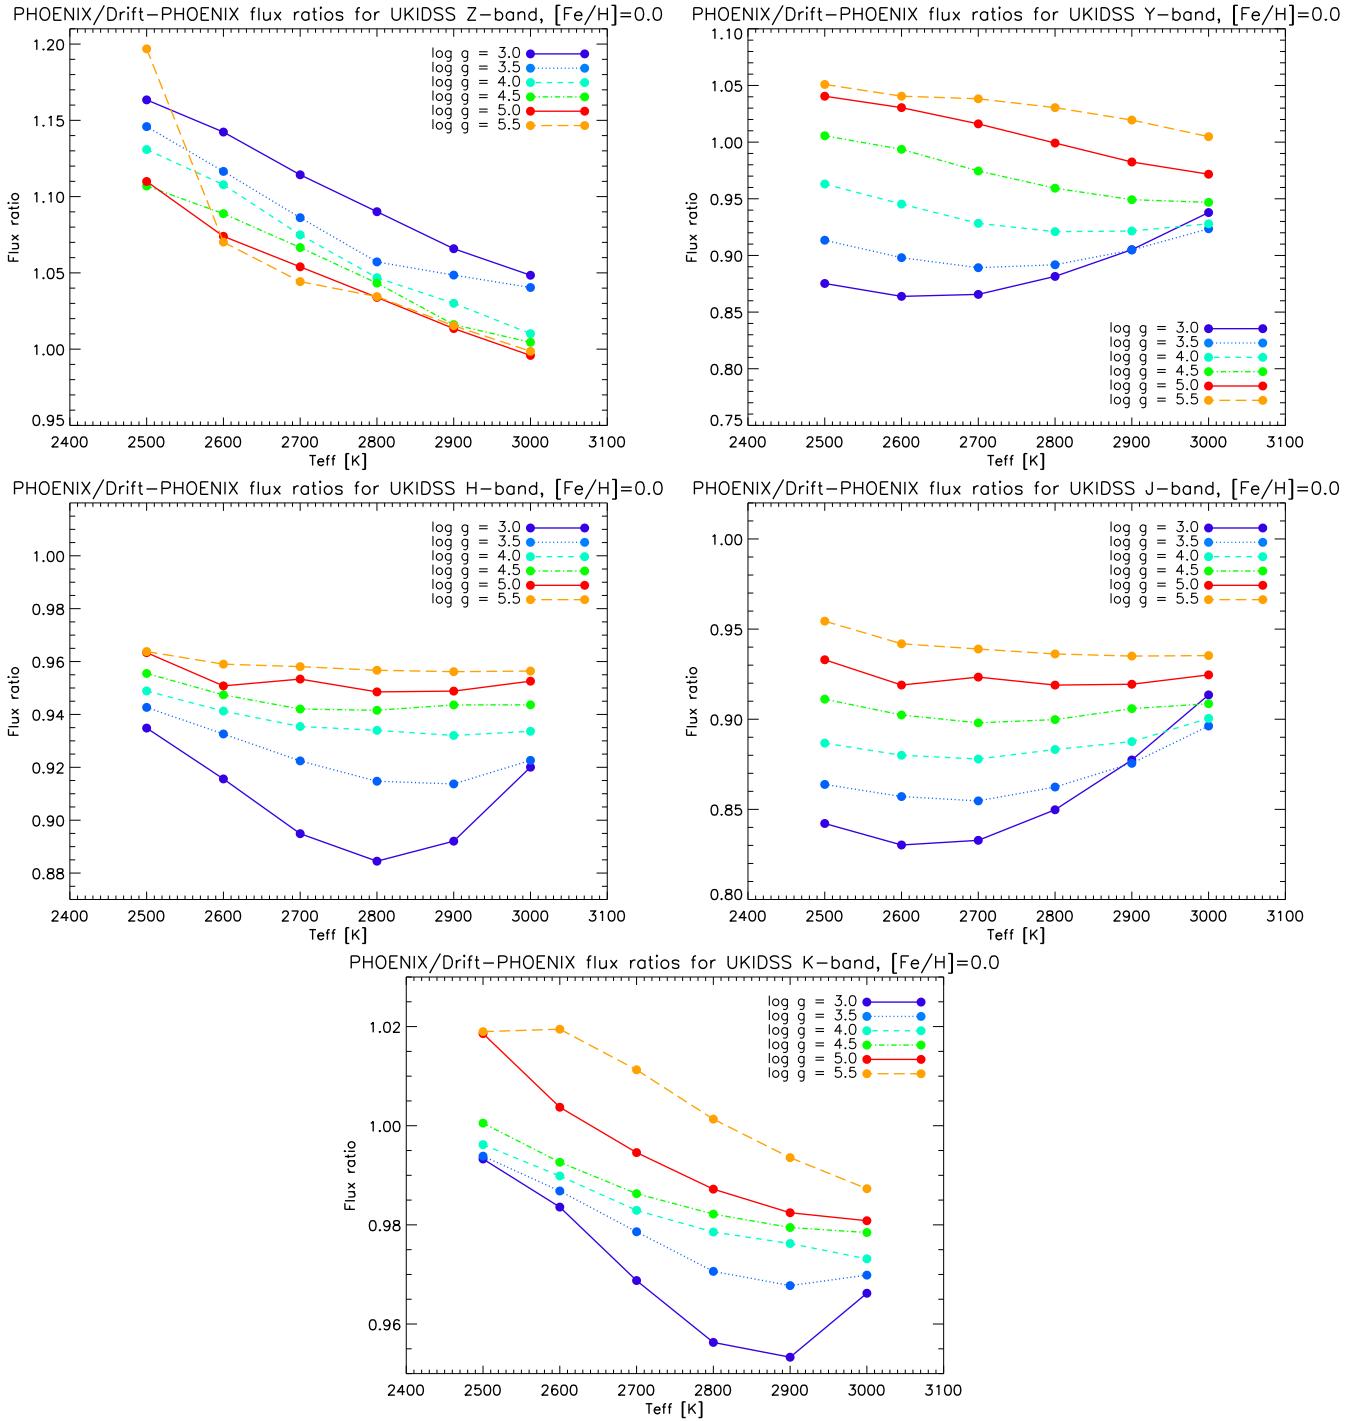

Figure 6. Convolved flux ratios for PHOENIX and DRIFT-PHOENIX atmosphere models for the UKIDSS filter system.

5 DISCUSSION

5.1 Different model assumption

The differences in the atmospheric ($T_{\rm gas}$, $p_{\rm gas}$)-structures and the resulting SEDs arises from differences in input data (element abundances, opacity sources), physical assumptions (mixing length, overshooting, dust/no dust), the choice of material values (equilibrium constants, line lists), but also from more technical details like convergence criteria and/or inner/outer boundary choices. It is outside the scope of this paper to identify in more detail why the

model atmosphere results differ as this would require a dedicated benchmark study.

The ATLAS atmosphere models were developed for hotter stars and cover a wide range of metallicities, surface gravities and effective temperatures, from hot O and B down to early-type M stars. The latest models use improved opacity distribution functions (ODFs) as described in Castelli & Kurucz (2004). The atomic and molecular line lists for the new ODFs are from the old Kurucz (1990) ODFs with some changes. A new TiO list from Schwenke (1998) is used. Additionally H$_2$O lines are adopted from Partridge
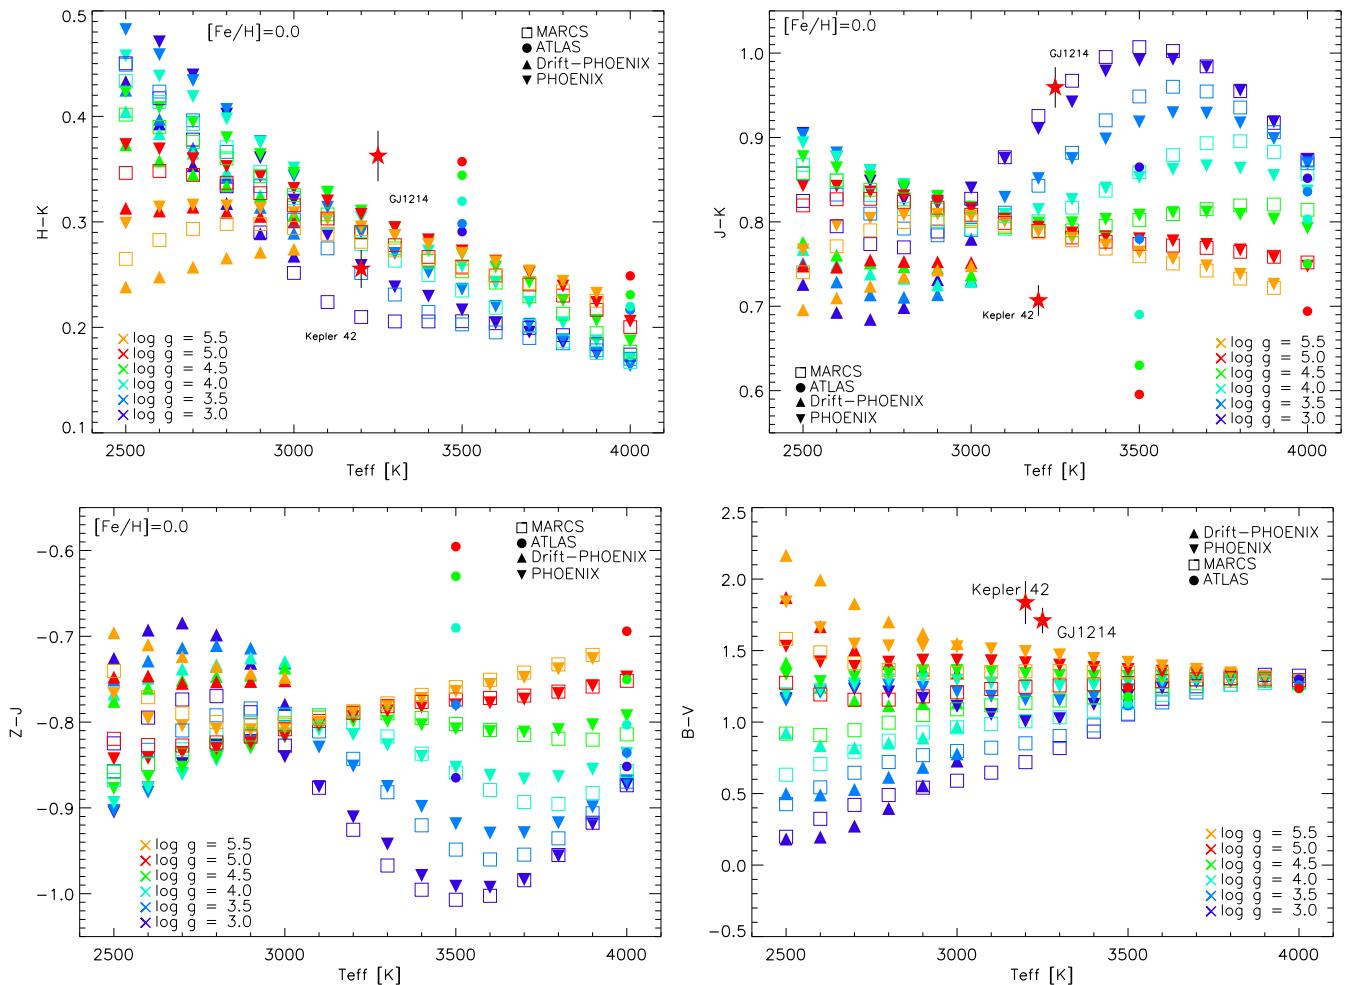

Figure 7. Colour indices versus effective temperature for all model atmosphere families (circles – ATLAS, squares – MARCS, lower triangles – PHOENIX, upper triangles – DRIFT-PHOENIX) of solar metallicity. The first three plots refer to the UKIDSS filter system. The two red stars are observed data for GJ 1214 and Kepler 42 (Cutri et al. 2003; Muirhead et al. 2012; Anglada-Escude et al 2013). The 2MASS measurements for these two stars have been shifted into the UKIDSS system using the transformations given in Hewett et al. 2006. Colour coding is used for different values for $\log(g)$ with a step of 0.5 dex. Top left: for lower T_{eff}, models with lower $\log(g)$ have higher $H-K$ values than models with high $\log(g)$. The trend inverses at higher temperatures. Top right: no clear trend with respect to $\log(g)$ is visible for lower T_{eff}. At higher temperatures models with lower $\log(g)$ show higher $J-K$ values. Bottom left: no trend for lower T_{eff}. At higher temperatures models with higher $\log(g)$ have higher $Z-J$ values. Bottom right: for low temperatures, models with high $\log(g)$ show a higher $B-V$ value. The $B-V$ difference with respect to $\log(g)$ diminishes for higher T_{eff}.

& Schwenke (1997). Furthermore extra bands have been added for some molecules such as CN, OH and SiO. Line list and ODFs can be found on Kurucz[6] and Castelli's[7] web pages. Element abundances are solar and adopted from Grevesse & Sauval (1998). The models are calculated assuming mixing-length theory (MLT) without overshooting, with a mixing length parameter $l/H_{\mathrm{p}} = 1.25$ and line-broadening by a microturbulent velocity of $v_{\mathrm{turb}} = 2.0$ km s^{-1}.

The MARCS models (Gustafsson et al. 2008) have focused on F, G and K stars extending into the M-dwarf regime. The opacity sampling method is used. Models are available for micro-turbulence velocities of $v_{\mathrm{turb}} = 0, 1, 2$ and 5 km s^{-1} (for comparison purposes with atlas, we have only considered a value of 2 km s^{-1}). The mixing length parameter value is $l/H_{\mathrm{p}} = 1.5$. The models are also divided in several metal abundance groups, out of which we consider the one with abundances from Grevesse et al. (2007). Molecular opacity sources include HCN, H_2O, C_2, C_3, C_2H_2, CH, CN, CaH, FeH,

MgH, NH, OH, SiH, SiO, TiO, VO and ZrO. Continuous absorption sources are H I, H$^-$, H$_2^-$, H$_2^+$, He I, He$^-$, C I, C II, C$^-$, N I, N II, N$^-$, O I, O II, O$^-$, Mg I, Mg II, Al I, Al II, Si I, Si II, Ca I, Ca II, Fe I, Fe II, CH, OH, CO$^-$ and H_2O^-. The codes also include collision-induces absorption from H I + H I, H I + He I, H_2 + H I, H_2 + H_2, H_2 + He I; continuous electron scattering and Rayleigh scattering for H I, H_2 and He I. The authors suggest that the only significant difference using different molecular opacity sources comes from CO, H_2O and TiO. CO sources adopted by (Gustafsson et al. 2008) (table 2) are from Goorvitch (1994) and Kurucz & Bell (1995), H_2O from Barber et al. (2006) and TiO from Plez (1998).

The PHOENIX models (Husser et al. 2013) are based on the Hauschildt & Baron (1999) stellar atmosphere code. The gas-phase chemistry is treated with the Astrophysical Chemical Equilibrium Solver (ACES; Witte et al. 2011). Husser et al. note that while condensation is included as element sink in the equation of state, it is omitted from opacity calculations and additionally no dust settlement is included in any of the models. The gas opacity species (line and continuum) are the same like in DRFIT-PHOENIX (see below). The

[6] http://kurucz.harvard.edu/

[7] http://wwwuser.oats.inaf.it/castelli/

code uses MLT, with $1/H_{\rm p} \sim 1.8$–3.5 for the M-dwarf parameter space. The microturbulent velocity is linked to the convective velocity that results from MLT. However, the microturbulent velocity it is only considered in the calculations of the high-resolution spectra, but not used for the computation of the atmospheric structure. Based on this assumption, $v_{\rm turb} < 1$ km s^{-1} for PHOENIX model atmospheres in the M-dwarf parameter range.

The DRIFT-PHOENIX models are aimed at brown dwarf and planet atmospheres. They are a combination of the PHOENIX atmosphere code (Hauschildt & Baron 1999), version 16.00.02A, and the DRIFT module (Helling, Woitke & Thi 2008b; Witte et al. 2009) that models cloud formation. DRIFT solves a system of element conservation and dust moment equations in phase non-equilibrium including the processes of dust nucleation, growth and/or evaporation. The influence of gravitational settling and element replenishment by convective overshooting is considered in relation to the formation processes. Six main elements are considered in these processes – Ti, O, Al, Fe, Si and Mg, together with the seven most important solids consisting of these elements – $TiO_2[s]$, $Al_2O_3[s]$, $Fe[s]$, $SiO_2[s]$, $MgO[s]$, $MgSiO_3[s]$ and $Mg_2SiO_4[s]$. The line opacity sources considered include H_2, CH, NH, OH, MgH, SiH, CN, SiO, CO_2, O_3, N_2^-O, CH_4, SO_2, NH_3, HCl, N_2, VO, CaH, CrH and FeH. Collision-induced absorption sources include $H_2 - H_2$, $H_2 - He$, $H_2 - CH_4$, $H_2 - N_2$, $N_2 - CH_4$, $N_2 - N_2$, $CH_4 - CH_4$, $CO_2 - CO_2$, $Ar - H_2$ and $Ar - CH_4$. CO lines are adopted from Goorvitch (1994), H_2O from Barber & Tennyson (2008) and TiO from Schwenke (1998). Mie and effective medium theory are applied to calculate the cloud opacity of mixed grains including the above-mentioned solid materials.

Only the PHOENIX and DRIFT-PHOENIX model families use the same line lists for gas opacity sources, and only MARCS and DRIFT-PHOENIX use the same values for the element abundances (Grevesse et al. 2007). It is therefore not surprising that the model fluxes differ particular for low $T_{\rm eff}$, where the influence of molecular and dust opacity is most prominent. In addition, there are differences in input parameter values such as the mixing length parameter. Husser et al. 2013 (their section 2.3.3) suggest that the microturbulent velocities does have no noticeable effect on the atmospheric structure computation results.

We further note that (Gustafsson et al. 2008) presented a comparison of the MARCS model atmospheres to ATLAS and PHOENIX (NextGen) model atmospheres as available at the time. Their comparison of the ($T_{\rm gas}$, $p_{\rm gas}$)-structures of MARCS and ATLAS model atmospheres for giants and supergiants for $\log(g) = 4.5$ and $T_{\rm eff} = 4000, 5000, 6000, 7000$ K did show a respectable agreement between the models. The same holds for their test of varying metallicities, and for a comparison to NextGen PHOENIX models with ($\log(g)$, $T_{\rm eff}$) = (0.0, 3000 K), (3.0, 5000 K). No radiation fluxes were compared. Plez (2011) presented comparison of synthetic Johnson–Cousins *UBVRIJHK* photometry and colours of MARCS, ATLAS and PHOENIX (NextGen) model atmospheres for $T_{\rm eff} = 3500$–8000 K. Plez (2011) demonstrate that differences do increase with decreasing $T_{\rm eff}$ particularly for $T_{\rm eff} < 4000$ K. Our study presented in this paper does support these findings and extend these early model comparisons into the M-dwarf regime.

5.2 Comparing synthetic photometry and observations

We compare the synthetic photometry for all three model atmosphere families with two observations.

(i) We compare the synthetic photometry results with observations for the M stars published in Koen et al. (2010).

(ii) The $B-V$, $J-K$ and $H-K$ colours of two observed M-dwarf planet host stars (Kepler 42, Muirhead et al. 2012; GJ1214, Anglada-Escude et al 2013) are included in Fig. 7 for comparison.

All objects of spectral type M, and for which optical and infrared photometry was available, were selected from tables 2 and 4 Koen et al. (2010) for our comparison. The majority of this sample of objects are early M stars with $T_{\rm eff} \approx 4000$ K and $\log(g) \approx 4.5$. Table C6 lists the names, associated photometric magnitudes and spectral types of all stars used for this comparison. Only the MARCS and the PHOENIX model families cover the respective parameter range. Fig. 8 presents a colour plot of the photometry that compares the MARCS and PHOENIX model results with the sample of observed M stars.

Early M-dwarfs are represented by model atmospheres with $T_{\rm eff} \approx 4000$ K, and the sample of observed M-dwarfs does not contain examples with $T_{\rm eff} < 3500$ K. Therefore, the upper half of the plot is empty, hence, it does not imply the models are giving incorrect predictions for these effective temperatures. The spectral type of the observed targets explains the lack of objects in the upper half of the plots and is not a mismatch between models and observations. For $\log(g)=4.5$ the median of the observed colours is well reproduced by the atmosphere models. For higher $\log(g)$, the observed colours are redder than predicted by atmosphere models. However, the scatter in the observations is larger than the differences in the models would suggest. The measurement uncertainties ~ 0.01 mag (Koen et al. 2010) are not big enough to account for the scatter in the observed data.

The reason for the differences between models and observations is not obvious. One reason could be a mismatch between the metallicities of the stars and the (solar) metallicity in the models. Note that not all objects in Fig. 8 have reliably measured metallicities, hence, the scatter of the observed data could be partly due to varying stellar metallicities. The comparison between the exoplanet host stars strengthens this hypothesis. While GJ1214 has approximately solar metallicity, Kepler 42 is reported to have sub-solar metallicity([Fe/H]=-0.48 ± 0.17 and [M/H]=-0.33 ± 0.12, Muirhead et al. 2012). GJ1214 is significantly redder in near-infrared colours than Kepler 42, but still only marginally consistent with the $H-K$ colour predicted from atmosphere models. Both objects are redder in $B-V$ than all predictions from the models.

Alternatively, the mismatch could be caused by physical processes not included in the models considered here, for example, effects related to the presence of strong magnetic fields (e.g. Vidotto et al. 2013). It has been shown that strong magnetic fields can alter the fundamental properties of cool stars, in particular, suppress the temperature and inflate the radius. A temperature suppression of up to 200–400 K is realistic for early M-type stars, see Stassun et al. (2012). This could possibly explain an increase of up to 0.1 mag in the $J-K$ colour (see Fig. 7). In summary, the best explanation for the scatter in the observed data points in Fig. 8 is probably a combination of a range of metallicities and the presence of magnetic fields, whereas the contribution from measurement uncertainties is only minor.

5.3 Implications of host-star's uncertainties for exoplanets

Estimating exoplanetary mass and radius directly depends on knowledge of the host star's mass and radius. Most often, they are derived by comparison to evolutionary models which, however, already carry the uncertainties in model atmospheres discussed in the previous sections. Stellar atmosphere models can provide values for surface gravity, $\log(g)$, but there is still a degeneracy in possible values for stellar mass and radius.
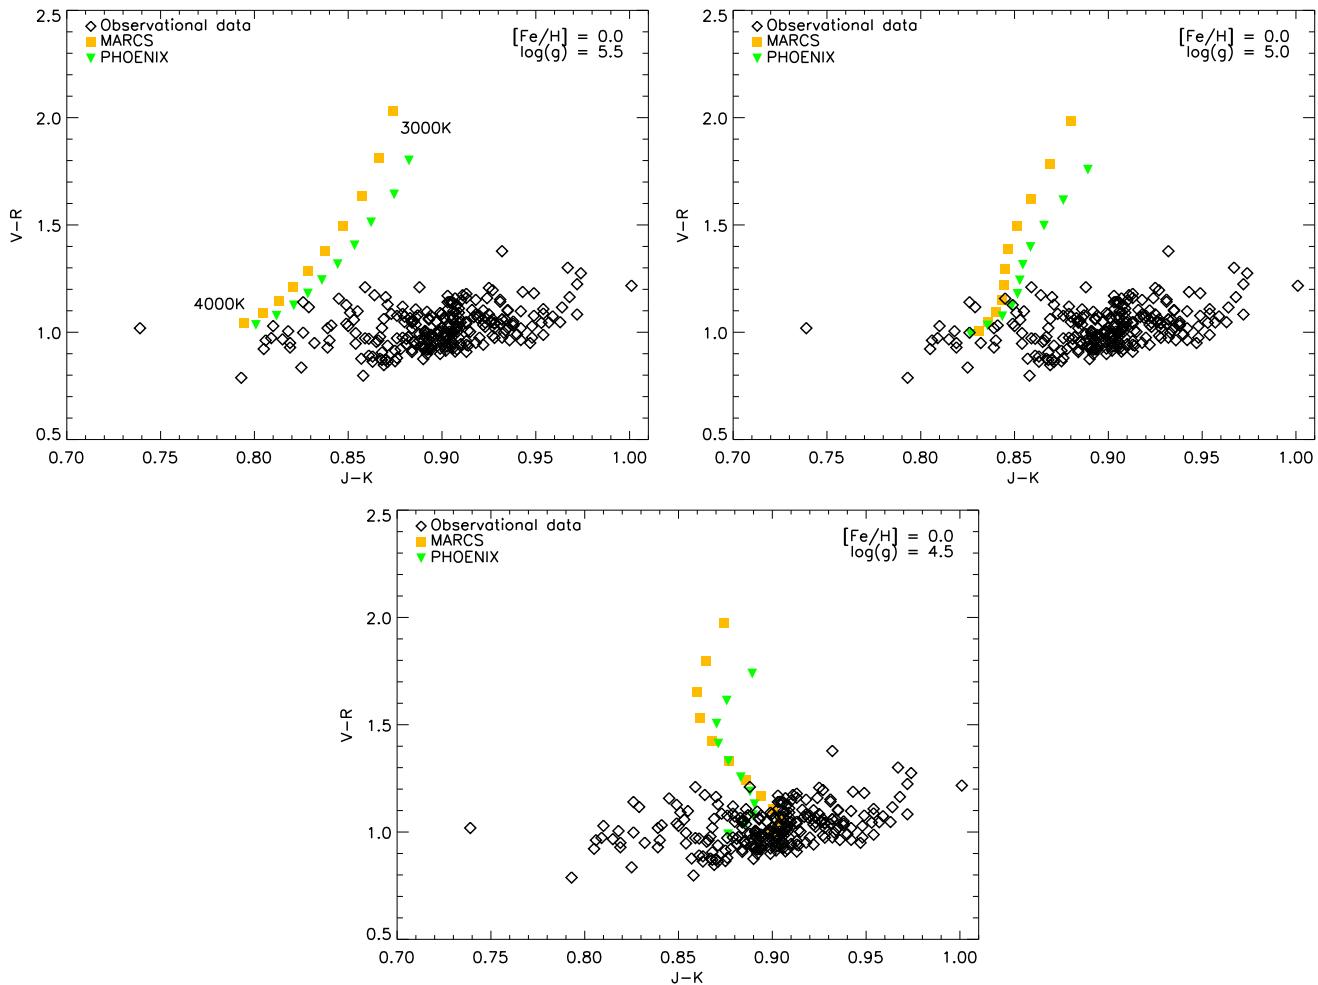

Figure 8. Colour–colour plot for a set of observed M stars (black diamonds, C6) and synthetic photometry of MARCS (yellow sqaures) and PHOENIX (green triangles) models for T_{eff} = 3000–4000 K, [M/H] = 0.0 and log(g) = 5.5–4.5. Each panel contains sets of models for a particular value of log(g). The model T_{eff} changes from 3000 K for higher y-axis values to 4000 K for lower y-axis values in each panel. Observed sample is adopted from the *UBVRI*, *JHK* photometry of Koen et al. (2010). It contains stars with various temperatures, surface gravity and metallicity values. The entire sample is plotted in all three panels. Typical observational uncertainty for the sample is ~0.01 mag for both, optical and infrared. The median of the observed colours is well reproduced by the log(g) = 4.5 atmosphere models. Scatter in the observations is larger than the differences in the models would suggest.

An important property for a star-planet(s) system is the HZ. The HZ refers to the distance away from the star where liquid water could exist on the surface of a planet, provided sufficient atmospheric pressure. Detailed calculations for the extent of the HZ have been conducted by Kasting, Whitmire & Reynolds (1993), Jones & Sleep (2010) and Kopparapu et al. (2013). Kane (2014) uses their methods to estimate the uncertainty of the HZs location (resulting from stellar parameter (effective temperature, radius, surface gravity, mass) uncertainties) for confirmed exoplanetary host stars and *Kepler* candidate hosts. The author demonstrates that ~ 5 per cent uncertainties in T_{eff} result in ~ 10 per cent uncertainty in the HZ location. Furthermore, the HZ distance is shown to have a linear dependence on the stellar radius R$_\star$ and hence proportional to $\sqrt{1/g}$ and $\sqrt{M_\star}$, where g and $M_\star$ are the stellar surface gravity and mass. The system Kepler 27 is used as an example where the host star's parameters have large uncertainties. The associated error in the HZ region is demonstrated to be large enough, so that a planet in HZ may very well lie outside of it on a 1σ level. The author further states that this is the case for the majority of *Kepler* candidates.

Plavchan, Bilinski & Currie (2014) compare transit durations of *Kepler* targets to a synthetic distribution crated based on

eccentricities of exoplanets discovered by the radial velocity method. The authors find an overabundance of *Kepler* targets with transit durations longer than expected and a median transit duration of ~25 per cent longer than predicted. These effects are both attributed to underestimates of the stellar radii. In addition, a statistically significant trend is found in the average transit duration as a function of stellar mass and radius which is explained by errors in determination of stellar radii as a function of spectral type.

A particularly underestimated factor for M-dwarfs is their strong magnetic field activity. The magnetic activity of the host star can have strong implications for the habitability of a planet. Vidotto et al. (2013) and Vidotto et al. (2014) address planetary magnetoshpere size in relation to the stellar magnetic fields and show that for non-axisymmetric stellar magnetic field topologies, the size of the planetary magnetosphere can expand/shrink by up to 20 per cent along its orbit. In addition, the authors argue that planets in systems around host stars with such magnetic field topologies will be better shielded against Galactic cosmic rays even in the absence of a thick planetary atmosphere or a large planetary magnetosphere.

6 SUMMARY

We compared ATLAS9, MARCS, PHOENIX and DRIFT-PHOENIX atmosphere models in the M-dwarf parameter range that includes young M-dwarfs and also brown dwarfs. Our study has been inspired by the first model atmosphere comparison in Gustafsson et al. (2008) and in Plez (2011) which focused on $T_{\rm eff} > 3500$ K, and by extensive studies for space missions as in Sarro et al. (2013). Our comparison of $(T_{\rm gas}, p_{\rm gas})$ structures for $T_{\rm eff} < 3500$ K reveals difference in local temperatures between the MARCS, PHOENIX and DRIFT-PHOENIX model atmosphere families of, on average, less than 300 K. Such a variation becomes significant for low $T_{\rm eff}$ models, where dust condensation plays a major role for the shape of the SED.

We compiled UKIDSS *ZYJHK*, 2MASS *JHKs* and Johnson *UBVRI* synthetic photometric data for the ATLAS, MARCS, PHOENIX, and DRIFT-PHOENIX model families. Colour indices differ between models by no more than 0.15 dex in the IR range. Both, atmospheric structure and synthetic photometry data, suggests that model atmospheres with higher surface gravity agree better between different models regardless of their $T_{\rm eff}$. Comparing to observational data, the difference in the models is smaller than the typical observational errors of 0.01 mag. However, a spread in the data is present which is not account for by the models, which may suggest a mismatch between model and stellar metallicities.

This paper demonstrated differences and similarities between various model atmosphere families which allows a better estimate of systematic uncertainty values that may result from our limited capacity of modelling every aspect of atmosphere physics and chemistry in the best possible way, and from the tentativeness of the 'best possible way'. Optimally, more than one model family should be used when working with observational data. The need for model atmosphere diversity has been demonstrated, for example, with respect to disc detection (Sinclair et al. 2010) or determining planetary parameter (Southworth 2012). Such studies suggest that a similar multimodel approach could be beneficial for studies as for example performed in Sarro et al. (2013), who present a module that will be used to detect and characterize ultracool dwarfs in the *Gaia* data base.

APPENDIX A: PARAMETER VALUES OF MODELS USED

Tables A1– A4 indicate availability of models of different families for various parameter value combinations.

The tables below describe the parameter values for all the models used in this work. Empty cells indicate that a given set of parameter values was not used as the corresponding model was missing in some model family.

Table A1. Common models between ATLAS and MARCS for $T_{eff} = 3500$ K.

log(g)[M/H]	−2.5	−2.0	−1.5	−1.0	−0.5	0.0	+0.5
3.0	X	X		X	X	X	X
3.5	X	X	X	X	X	X	X
4.0	X	X	X	X	X	X	X
4.5	X	X	X	X	X	X	X
5.0	X	X	X	X	X	X	X

Table A2. Common models between ATLAS and MARCS for $T_{eff} = 4000$ K.

log(g)[M/H]	−2.5	−2.0	−1.5	−1.0	−0.5	0.0	+0.5
3.0	X	X	X	X	X	X	X
3.5	X	X	X	X	X	X	X
4.0	X	X	X	X	X	X	X
4.5	X	X	X	X	X	X	X
5.0	X	X	X	X	X	X	X

Table A3. Common models between MARCS, PHOENIX and DRIFT-PHOENIX for [M/H] = 0.0.

log(g)T_{eff}	2500	2600	2700	2700	2800	2900	3000
3.0	X	X	X	X	X	X	X
3.5	X	X	X	X	X	X	X
4.0	X	X	X	X	X	X	X
4.5	X	X	X	X	X	X	X
5.0	X	X	X	X	X	X	X
5.5	X	X	X	X	X	X	X

APPENDIX B: COMPLEMENTARY T–P STRUCTURE AND FLUX RATION PLOTS

Figure B1 presents a sample of plots illustrating the difference in temperature–pressure structures between ATLAS and MARCS models in the metallicity parameter space. Figure B2 gives synthetic flux ratios in the optical bands for the ATLAS and MARCS models.

APPENDIX C: SYNTHETIC FLUX AND COLOUR DATA

Table C1 summarizes the filter wavelength ranges where throughput values are above 1 per cent for the systems used in this study. Table C2–C5 provide a complete set of synthetic fluxes for all models discussed in this work. Table C6 contains photometric data for the sample M-dwarfs used for the comparison with synthetic colours in Section 5.2.

Table A4. Additional common models between MARCS, PHOENIX for [M/H] = 0.0.

log(g)T_{eff}	3100	3200	3300	3400	3500	3600	3700	3800	3900	4000
3.0	X	X	X	X	X	X	X	X	X	X
3.5	X	X	X	X	X	X	X	X	X	X
4.0	X	X	X	X	X	X	X	X	X	X
4.5	X	X	X	X	X	X	X	X	X	X
5.0	X	X	X	X	X	X	X	X	X	X
5.5	X	X	X	X	X	X	X	X	X	X
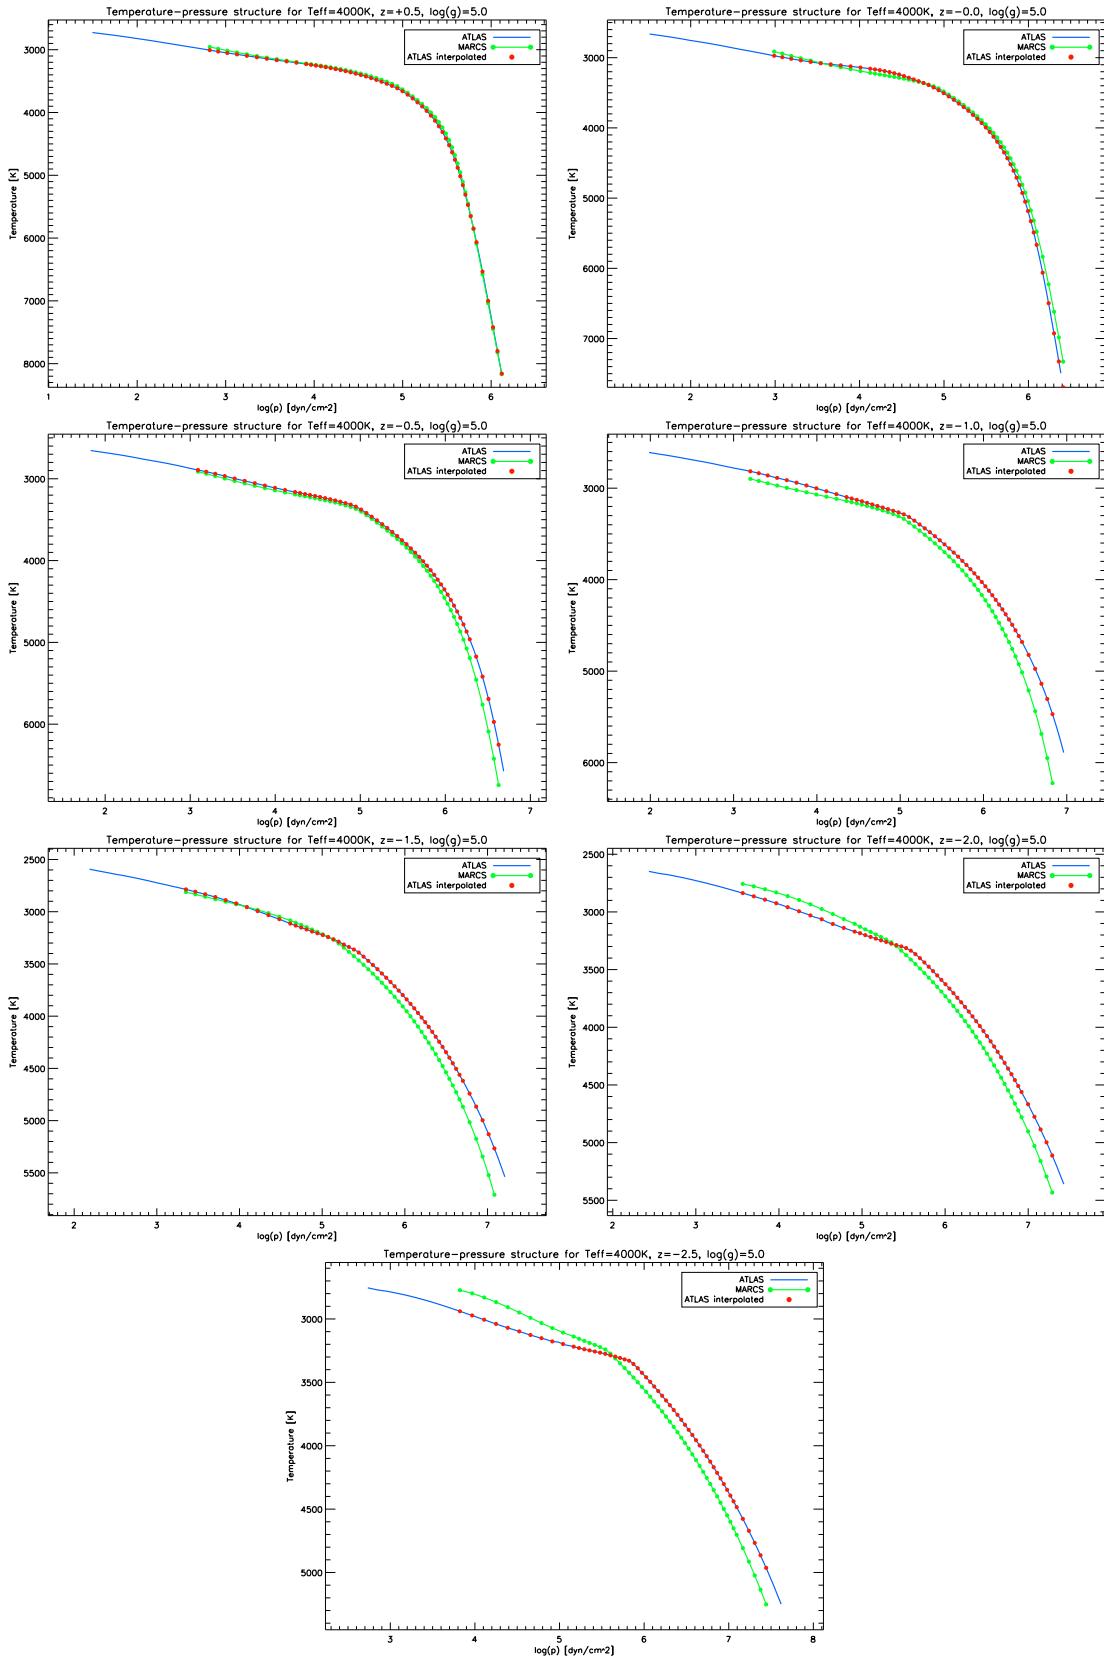

Figure B1. Local temperature–pressure structures of the ATLAS and MARCS models for $T_{\rm eff} = 4000$ K, $\log(g) = 5.0$ and various metallicity values.
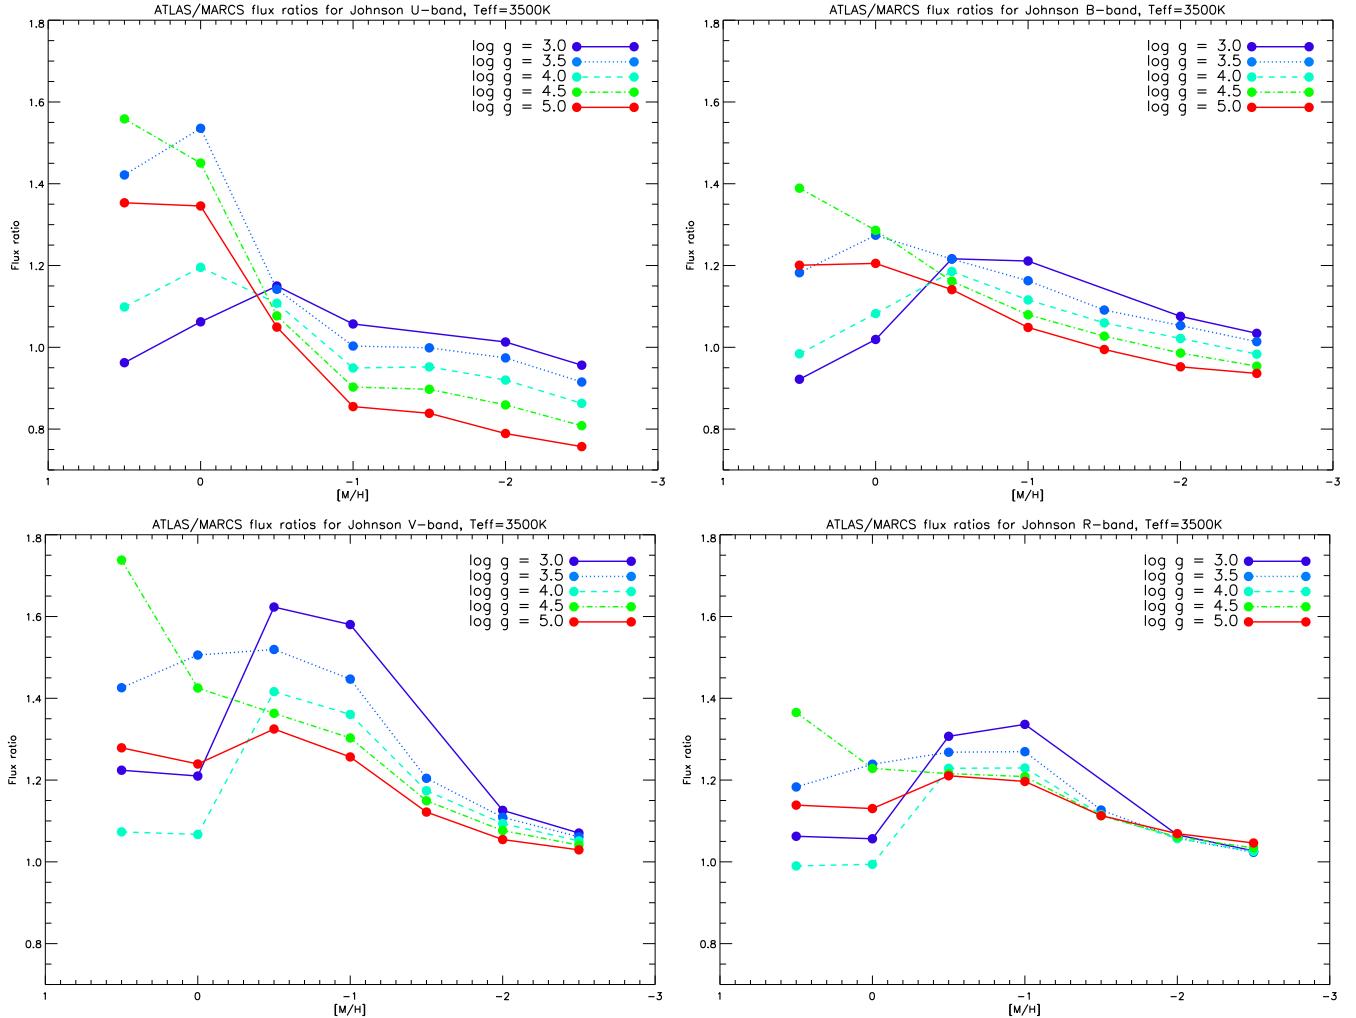

Figure B2. Synthetic flux ratios between for ATLAS/MARCS models in the optical Johnson UBVR bandpasses for $T_{\mathrm{eff}} = 3500$ K.
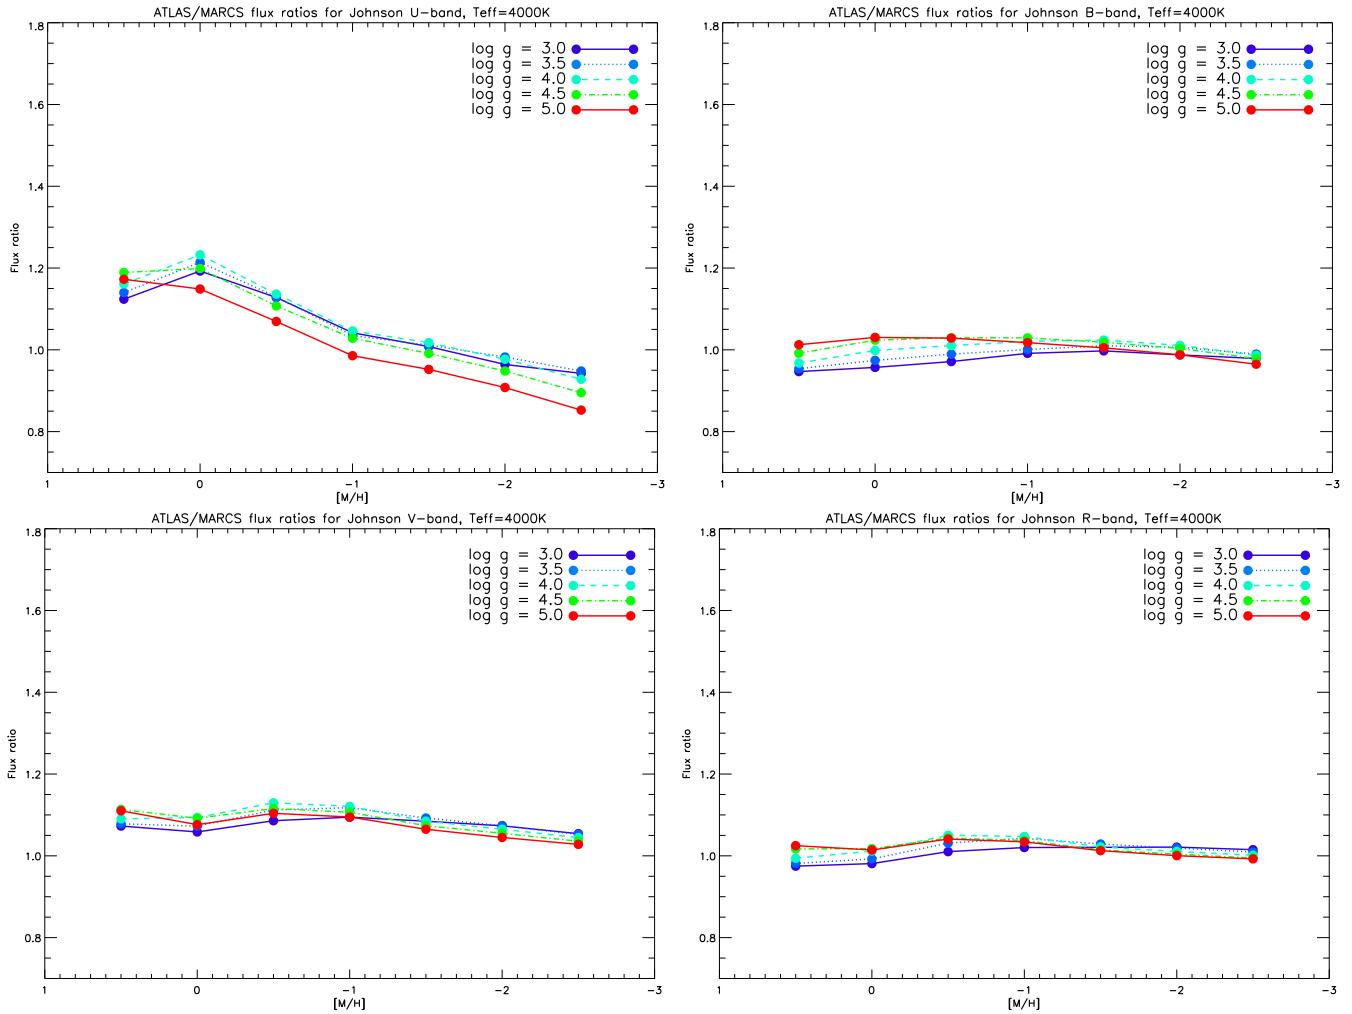

Figure B3. Synthetic flux ratios between for ATLAS/MARCS models in the optical Johnson UBVR bandpasses for $T_{\mathrm{eff}} = 4000$ K.

Table C1. Wavelength range for filters used for synthetic photometry. The range is given for throughput values above 1 per cent.

Filter	Wavelength range
UKIDSS Z	0.82–0.94 μm
UKIDSS Y	0.96–1.10 μm
UKIDSS J	1.15–1.35 μm
UKIDSS H	1.45–1.82 μm
UKIDSS K	1.96–2.44 μm
2MASS J	1.08–1.41 μm
2MASS H	1.48–1.82 μm
2MASS Ks	1.95–2.36 μm
Johnson U	3050–4100 Å
Johnson B	3700–5500 Å
Johnson V	4700–7300 Å
Johnson R	5250–9450 Å
Johnson I	6900–11800 Å

Table C2. Complete set of PHOENIX synthetic fluxes for models of solar metallicity. The values in the filter columns correspond to $-2.5\log(F_{R1}/F_{R1,\mathrm{Vega}})$, where $R1$ is the corresponding filter. Column 3–7 refer to the Johnson and columns 11–15 to the UKIDSS filters.

T_{eff}	$\log(g)$	U	B	V	R	I	2MASS H	2MASS J	2MASS Ks	H	J	K	Y	Z

Table C3. Complete set of MARCS synthetic fluxes for models of solar metallicity. The values in the filter columns correspond to $-2.5 \log(F_{R1}/F_{R1,\text{Vega}})$, where $R1$ is the corresponding filter. Column 3–7 refer to the Johnson and columns 11–15 to the UKIDSS filters.

Table C4. Complete set of DRIFT-PHOENIX synthetic fluxes for models of solar metallicity. The values in the filter columns correspond to $-2.5 \log(F_{R1}/F_{R1,\text{Vega}})$, where $R1$ is the corresponding filter. Column 3–7 refer to the Johnson and columns 11–15 to the UKIDSS filters.

Table C5. Complete set of ATLAS synthetic fluxes for models of solar metallicity. The values in the filter columns correspond to $-2.5 \log(F_{R1}/F_{R1,\text{Vega}})$, where $R1$ is the corresponding filter. Column 3–7 refer to the Johnson and columns 11–15 to the UKIDSS filters.
