ABSTRACT

U-Pb detrital zircon ages from Mesoproterozoic and Cambrian siliciclastic units in west Texas (USA) constrain the depositional setting, provenance, and tectonic history of the region within a late Mesoproterozoic Grenville foreland basin and the early Paleozoic Sauk transgressive sequence. Two key units, the Hazel and Lanoria Formations, have detrital zircon age spectra dominated by detritus derived from the Grenville orogen (the Llano uplift and eroded equivalents), the ca. 1.4 Ga Granite-Rhyolite, and the ca. 1.7–1.6 Ga Yavapai/Mazatzal provinces. These data, combined with sedimentological data, permit interpreting those formations as the proximal and distal deposits, respectively, of a molasse shed into the Grenvillian foreland basin.

Detrital zircons as young as ca. 520 Ma show that the Van Horn Formation, previously considered to be Precambrian in age, is no older than middle Cambrian. Further, the overall detrital zircon age spectrum of the Van Horn Formation is similar to that of the overlying Cambro-Ordovician Bliss Formation: both indicate derivation from sources that included the Colorado-Oklahoma aulacogen, Grenville, Granite-Rhyolite, and Yavapai/Mazatzal provinces. The similarities between the depositional history of the Van Horn and Bliss Formations lead us to conclude that the base of the Sauk Sequence in west Texas occurs at the base of the Van Horn Formation. Base-level rise associated with the Sauk transgression affected drainage patterns and sediment deposition along southwestern Laurentia some 20 m.y. earlier than previously assumed.

—Christopher J. Spencer

INTRODUCTION

The Grenville orogeny is a record of the assembly of the supercontinent Rodinia. In Laurentia, syn-collisional detritus shed off the evolving Grenville deformation front is preserved in a variety of settings, ranging from widely dispersed extensional basins (e.g., Midcontinent Rift, Fort Wayne Rift) to broad, fluvial aprons hundreds to even thousands of kilometers in width (Cawood et al., 2007; Hadlari et al., 2012; Rainbird et al., 2012, and references therein). In contrast, the preserved lateral extent of foreland basin deposition (as defined by Allen and Allen, 2005) is thought to be limited to a small number of localities proximal to the Grenville thrust front (Santos et al., 2002; Cawood et al., 2007; Baranowski et al., 2009; Rainbird et al., 2012). In west Texas (USA), the late Mesoproterozoic Lanoria and Hazel Formations have been interpreted as having formed in extensional basins (Bickford et al., 2000) or as proximal molasse (Soegaard and Callahan, 1994). Consequently, those units should contain a provenance fingerprinting their connection to source terranes exhumed by the Grenville orogeny. We use laser ablation inductively coupled plasma–mass spectrometry (ICP-MS) detrital zircon U-Pb geochronology to assess this prediction and as a potential test of correlations of the formations in west Texas.

Nearly 300 m.y. after the assembly of Rodinia, the supercontinent fragmented. The initial episode of rifting along Laurentia’s margins began in the early Neoproterozoic (ca. 780–740 Ma), and extensional tectonism continued for nearly 250 m.y. (Macdonald et al., 2013, and references therein). Thermal subsidence analyses have revealed that, despite this protracted period of continental rifting, the rift-to-drift transition occurred near the time of the Precambrian-Cambrian boundary along both the eastern and western margins of Laurentia (ca. 540 Ma) (Armin and Mayer, 1983; Bond and Kominz, 1984; Williams and Hiscott, 1987; Cawood et al., 2001). This is recorded by the progressive onlap and blanketing of North America as preserved in the Sauk Sequence (Sloss, 1963).

The stratigraphic location of the base of the Sauk Sequence has been one of prolonged debate and has generally been ascribed on the basis of sedimentology and biostratigraphy (e.g., Hogan et al., 2011; Peters and Gaines, 2012). In west Texas and New Mexico, its position is placed at the base of the Cambrian–Ordovician Bliss Formation (Hayes, 1972; Amato and Mack, 2012). In New Mexico, this surface is a nonconformity with Mesoproterozoic igneous and metamorphic rocks or the Cambrian Florida Mountains pluton (Clemens, 1988). In west Texas, however, the Bliss Formation overlies the braided fluvial sandstones of the Van Horn Formation, the age of which has been ambiguous but typically considered to be latest Precambrian (Denison, 1980; Davidson, 1980) because of the lack of trace- or macrofossils. We use detrital zircon U-Pb ages in the Van Horn Formation to assess its maximum depositional age and relation of the Van Horn Formation to the location of the basal Sauk Sequence in west Texas.

GEOLOGICAL SETTING

Pre–1.3 Ga Rocks

Pre–1.3 Ga basement rocks in the southwestern United States belong to the 1.8–1.6 Ga Yavapai/Mazatzal and 1.5–1.3 Ga Granite-Rhyolite provinces (Fig. 1). These units incorporate arc and arc-related supracrustal rocks as well as A-type granites emplaced behind active continental arcs during intra- and back-arc extension (Karstlom and Bowring, 1993; Staglazi et al., 2009).

Grenville Orogeny and Sedimentation

Along the southeast Laurentian margin, the Grenville orogeny (Rivers, 1997; Carr et al., 2000; Chiarenzelli et al., 2010) is attributed to...
collision with the Kalahari and/or Amazon cratons (Dalziel et al., 2000; Tohver et al., 2006; Jacobs et al., 2008; Hynes and Rivers, 2010). This orogenic episode is archived in rocks forming the broad Grenville province in southeastern Canada, inliers in the Appalachian Mountains, and the Llano uplift of central Texas (Fig. 1) where three main phases of magmatic activity are known: arc volcanism and accretion between 1288 and 1232 Ma, collision-related magmatism between 1150 and 1120 Ma, and post-collisional magmatism between 1120 and 1070 Ma (Mosher, 1998).

In west Texas, exposures of Precambrian rocks are restricted to the Franklin Mountains north of El Paso, and the region around Van Horn (Fig. 2). The former contains a metasedimentary succession ~1200 m thick (Fig. 3), consisting of the basal Castner Marble, the overlying and laterally discontinuous volcanic Mundy Breccia (Bickford et al., 2000), and the Lanoria Formation, a ~700-m-thick succession of shallow marine sandstone and mudstone (Shannon et al., 1997; Seeley, 1999). These units are capped by the trachytic to rhyolitic ignimbrites and lavas of the Thunderbird Group with a zircon isotope-dilution–thermal ionization mass spectrometry (ID-TIMS) U-Pb age of 1111 ± 53 Ma (Roths, 1993). The Red Bluff Granite intrudes the entire sequence and has yielded a zircon ID-TIMS U-Pb age of 1120 ± 35 Ma (Shannon et al., 1997).

In the Van Horn area, the post-1.3 Ga stratigraphy (Fig. 3) begins with the limestone-bearing Allamoore Formation, which contains a tuff with zircon ID-TIMS U-Pb ages of 1256 ± 5 Ma (Bickford et al., 2000) and 1255 ± 2 Ma (Timmons et al., 2005) and is considered to be broadly equivalent to the Castner Marble as well as with the Bass Limestone in the Grand Canyon. Overlying the Allamoore is the Tumbledown Formation, a unit of volcanic and carbonate breccia in which a felsic tuff near the top of the formation has yielded an ID-TIMS U-Pb zircon age of 1243 ± 10 Ma (Bickford et al., 2000). The Tumbledown Formation is overlain by the Hazel Formation, which is a ~3000-m-thick unit of conglomerate and interbedded fine-grained sandstone whose thickness decreases significantly to the north (Bickford et al., 2000).

The initial Neoproterozoic rifting of the western margin of Laurentia is recorded by a ca. 780 Ma magmatic event stretching from Utah to the Yukon (Jefferson and Parrish, 1989; Harlan et al., 2003; Dehler et al., 2010; Spencer et al., 2012; Mahon et al., 2014; Kingsbury-Stewart et al., 2013), whereas rifting and associated magmatism along the eastern Laurentian margin occurred between 760 and 700 Ma (Su et al., 1994; Aleinikoff et al., 1995; Tollo and Hutson, 1996). Thermal subsidence studies show that the eventual rift-to-drift transition occurred along both margins at ca. 620–550 Ma (Williams and Hiscott, 1987; Levy and Christie-Blick, 1991; Thomas, 1991; Aleinikoff et al., 1995; Cawood et al., 2001; Cawood and Pisarevsky, 2006).

**Sauk Transgression**

The breakup of Rodinia and subsequent thermal subsidence of the Laurentian margins facilitated deposition of a thick sequence of largely marine sediments (e.g., Bond and Konmiz, 1984; Levy and Christie-Blick, 1991). These define the Sauk Sequence (Sloss, 1963), which spans the late Neoproterozoic to mid-Ordovician and blankets approximately half of North America (outcrop and borehole data; Peters and Gaines, 2012).

The Sauk Sequence overlies progressively older units craterward, from rift/post-rift–related Neoproterozoic sequences along the margins of Laurentia to Archean–Proterozoic basement in the central regions of the craton (Rankin, 1993). This transgressive episode was long lived, with the base of the Sauk Sequence being ~30–40 m.y. younger in the craton interior than at the margins. In west Texas, the base of the Sauk Sequence has been placed at the base of the Cambro-Ordovician Bliss Formation (Hayes, 1972), but, as detailed herein, we suggest it should be placed at the base of the underlying Van Horn Formation.

**Van Horn Formation**

The Van Horn Formation near its type locality in Texas consists of >500 m of conglomerate with varying amounts of interbedded sandstone and, largely because it is devoid of macro- and trace fossils, has been considered to be Precambrian in age (King and Flawn, 1953). It is arkosic and contains abundant lithic fragments derived from the felsic volcanic rocks of the Thunderbird Group (and its equivalents, e.g., metavolcanic rocks at Pump Station Hills; Thomann, 1981), as well as from the underlying Hazel Formation, and is interpreted as recording deposition in a system of coalescing...
alluvial fans marked by high-gradient streams (McGowen and Groat, 1971). Where exposed, the Van Horn Formation can be seen to infill and mantle an irregular paleotopography formed on the underlying Hazel Formation.

### Bliss Formation and Ordovician Carbonates

The Bliss Formation in Texas is 30–80 m thick and consists of medium- to fine-grained quartzitic arenite (LeMone, 1969; Davidson, 1980). The contact between the Bliss and the Van Horn has not been resolved and is variously ascribed to being unconformable or depositional (McGowen and Groat, 1971). On the basis of trilobite and conodont biostratigraphy, the Bliss Formation is known to be upper Cambrian to Lower Ordovician in age (Taylor et al., 2004). Overlying the Bliss Formation is a thick sequence of Ordovician carbonate rocks documenting the final stages of the Sauk transgression (Hayes, 1972) (Fig. 3).

### METHODS AND RESULTS

Four ~5 kg sandstone samples were collected from the Van Horn and Franklin Mountain regions of west Texas within the Lanoria, Hazel, and Van Horn Formations. Zircons were extracted using standard techniques (i.e., Wilfley table, heavy liquid, Franz magnetic separation), mounted in epoxy resin, and polished to expose the interior of the grains. Zircons were imaged using cathodoluminescence (CL) and back-scattered electron (BSE) techniques (Fig. 4) prior to analysis. Zircon U-Pb geochronology was performed by LA–single-collector (SC)–ICP–MS at the NERC Isotope Geosciences Laboratory (NIGL), Keyworth, United Kingdom. All unknown and standard data are reported in the GSA Data Repository.1

The instrumentation used for analyses comprises a Nu Instruments Attom single-collector high resolution–ICP-MS-coupled to a New Wave Research UP193 solid-state laser ablation system; the full method is described in Thomas et al. (2013). Laser ablation was accomplished

Figure 3. Stratigraphy of the Mesoproterozoic to Cambrian rocks of the Franklin Mountains and Van Horn areas (after Davidson, 1980; Bickford et al., 2000). Westward onlap of the Van Horn Formation inferred from this study. Radiometric ages (marked with stars) are from Shannon et al. (1997) and Bickford et al. (2000). Locations of detrital zircon samples used in this study are marked with circles. ID-TIMS—iso-dilution–thermal ionization mass spectrometry; ICP-MS—inductively coupled plasma–mass spectrometry.

with a 25- or 35-μm-diameter spot size with a laser fluence of 2.0–2.2 J/cm² at 10 Hz for 15 seconds of integration (December 2012) or 5 Hz for 30 seconds (November 2013). On-peak dwell times were adjusted to give the best precision on the Pb/Pb and U/Pb ratios for an average zircon composition: 200 μs on 206Hg, 206Pb, 207Hg, 207Pb, 208Hg, and 208Pb, with 3 ms on 204Hg, 204Pb, 206Hg, 206Pb, and 207Pb. The Pb/Pb and U/Pb ratios were normalized to bracketing primary reference materials of 91500 and GJ-1, on the basis of the average measured value of the reference materials compared to the ratio determined by ID-TIMS (Wiedenbeck et al., 1995; Jackson et al., 2004; see also DR2). All Pb/Pb and U/Pb reference material analyses have an external reproducibility of 1%–2% (2 standard deviations). Analyses significantly above 204Pb (common lead) detection limits (~600 cps) were rejected.

Systematic uncertainties were propagated using quadratic addition incorporating the internal and external reproducibility of the reference material during each analytical session; these are the isotopic uncertainties of the reference material as determined by ID-TIMS, long-term excess variance of the NIGL Nu Atom SSC-ICP-MS, and decay constant uncertainties (e.g., Schoene et al., 2006).

Given the natural break in U-Pb ages between ca. 1000 and 500 Ma concordance is defined for ages above 700 Ma using the ratio of 206Pb/238U and 207Pb/206Pb ages, and 206Pb/238U and 207Pb/206Pb ages are used for those younger than 700 Ma. The accepted ages were selected from a 95% concordant subset, wherein the 206Pb/238U and 207Pb/206Pb ages are used for zircons younger and older than 700 Ma, respectively; this age was chosen because there is a natural gap in the ages of the zircons in these samples. Visualization of U-Pb concordia and zircon ages is achieved using Isopo 4.0 (Ludwig, 2003) and densityplotter software (Vermesch, 2012) (Figs. 5 and 6). GPS locations of samples are presented in Table 1.

**Lanoria Formation**

One sample of the Lanoria Formation (sample CS12-1) was collected along the Transmountain Road (Fig. 2) from the L3 member of Seeley (1999) in the Franklin Mountains. The sample is a fine- to medium-grained quartz arenite with well-rounded grains and abundant trough and planar cross-bedding. Zircons are mainly colorless with moderate degrees of rounding and sphericity and range in size from 80 to 300 μm (Fig. 4). Zircons from this sample yield an age distribution with three main populations at 1235, 1460, and 1840 Ma (206Pb/238Pb), and subordinate populations of 1.6 Ga and Neoarchean ages (Figs. 5 and 6). Although only 115 of the 172 analyses were <5% discordant [using (206Pb/238U age) / (207Pb/206Pb age)], all analyses have the same age distributions as the concordant subset. The youngest zircon (1124 ± 28 Ma, 3% discordant) was reanalyzed three times following a re-polishing of the initial ablation pit, which yielded all concordant analyses (<2% discordant). The weighted mean of the four analyses is 1094 ± 9 Ma (mean square weighted deviation, [reduced chi-squared] MSWD = 0.9).

**Hazel Formation**

One sample from the Hazel Formation (sample CS12-4) was collected from the upper sandstone unit in the Millican Hills (Fig. 2) of the Van Horn area. The sample is composed of a fine- to coarse-grained litharenite with subrounded sand grains. Zircons from this sample are euhedral to well rounded, range from dark purple to light pink in color, and are 70–500 μm in size.

The zircon age distributions show one dominant population at 1120 Ma, with two subordinate peaks at 1440 and 1800 Ma (Figs. 5 and 6). There is also a large population of discordant analyses with ca. 1200 Ma 206Pb/238Pb ages. Similar to the Lanoria Formation sample CS12-1, nearly half (64 out of 121) of the analyses are discordant (>5% discordant), although the discordant age peaks show no major differences from those that are concordant.

---

**Figure 4.** Cathodoluminescence (CL) images with analytical spots and associated ages (in Ma) in representative zircon grains from each sample. CL images have been adjusted only for brightness and contrast.
Van Horn Formation

Two samples were collected from the Van Horn Formation from the southern end of the Millican Hills northwest of the town of Van Horn. One sample was from near the base of the formation (CS12-5) and the other was taken one meter below the contact with the overlying Bliss Formation (CS12-3) (Fig. 2; see Table 1 for geographic locations). Both samples are coarse-grained arkoses with small pebbles (<0.5 mm) of volcanic fragments derived from the underlying Hazel Formation; the fragments are more abundant in the lower sample. Zircons in both samples are mostly light pink to colorless and range from euhedral to subrounded with several angular fragments. The zircons from the lower Van Horn Formation are 80–900 μm in size, and those from the upper part of the formation range from 50 to 500 μm.

The age distribution from the lower Van Horn is similar to the age distribution of the underlying Hazel Formation, with dominant age peaks at 1060 and 1400–1480 Ma and a few late Paleoproterozoic grains (Figs. 5 and 6). Similar to the Hazel Formation, there is also a large number of discordant ca. 1180 Ma analyses; the total number of concordant (<5% discordant) zircon analyses is 36 of 139 in the lower sample (CS12-5) and 75 of 150 in the upper sample (CS12-3). The upper Van Horn hosts a similar zircon age spectrum (major and subordinate peaks at 1080 and 1400 Ma, respectively), but with an additional variably discordant age population at ca. 520 Ma (see DR1). Each of the youngest zircons were reanalyzed multiple times following a re-polishing of the initial ablation pit. They yielded concordant analyses (<1% discordant) ranging between 509 ± 13 and 533 ± 12 Ma (207Pb/235U). The weighted means of the four youngest grains overlap within error and are 522 ± 6 Ma (n = 4; MSWD = 1.9), 521 ± 6 Ma (n = 6; MSWD = 2.0), 519 ± 10 Ma (n = 2; MSWD = 0.1), and 527 ± 8 Ma (n = 3; MSWD = 0.2) (Fig. 7). The weighted average of all the analyses of the youngest four grains (n = 15) is 522 ± 7 Ma (MSWD = 0.3). It should be noted, however, that a weighted average of a single detrital population assumes that all of the youngest zircons came from a single igneous source of a single age, which is extremely unlikely and ultimately untestable.

DISCUSSION

Provenance and Correlation of the Lanoria and Hazel Formations

The post-Grenvillian detrital zircon age spectra of the Lanoria and Hazel Formations are similar and can be linked to proximal provenance areas along the Grenville/Llano deformation front and the Granite-Rhyolite and Yavapai/Mazatzal provinces (see Fig. 2). The offset in the Grenvillian-age peak from 1120 Ma in the Hazel Formation to 1235 Ma in the Lanoria...
Quartzite likely reflects derivation from different portions of the Grenville orogen. The youngest single-grain (<1% discordance) detrital zircons from the Lanoria and Hazel Formations are 1094 ± 9 (weighted mean of 4 analyses) and 1079 ± 27 Ma, respectively. A minimum age of the Streeruwitz thrust. This thrust fault emplaces pre-1.3 Ga Carrizo Mountain Group rocks on top of the formation, and hornblende from the basal mylonite yields an 40Ar/39Ar age of ca. 1035 Ma (Bickford et al., 2000). The minimum age of the Lanoria Formation is constrained by the cross-cutting Red Bluff Granite which is imprecisely dated at 1120 ± 34 Ma. The youngest detrital zircon in the Lanoria Formation is within uncertainty of the intrusion age of the Red Bluff Granite (albeit with a younger mean). Despite this, the maximum depositional age of 1094 ± 9 Ma for the Lanoria Formation should be used with caution, and if the 1094 Ma zircon does constrain the maximum depositional age, then the two formations may be contemporaneous.

Depositional Model for West Texas Grenvillian Sedimentation

The Hazel Formation is mostly composed of clast-supported pebble conglomerate with minor interbeds of planar-laminated to cross-bedded sandstone and thin mudstone layers having desiccation cracks attesting to subaerial deposition (Soegaard and Callahan, 1994). Systematic variation of pebble composition in the Hazel Formation defines a shift in source material from dominantly footwall to hanging-wall derivation as the Streeruwitz thrust exhumed the Grenvillian basement (Soegaard and Callahan, 1994). The Lanoria Formation outcrop belt is ~180 km northeast from that of the Hazel Formation. Its facies character, paleocurrent data, and significant northward thinning suggest that sediment was shed from southern highlands (present coordinates) onto a wave- and tide-dominated marine platform (Seeley, 1997, 1999). Previous interpretations have considered the Lanoria and the Hazel Formations as being temporally discrete units (e.g., Bickford et al., 2000; Timmons et al., 2005). Given our findings, with both units displaying similar age spectra and depositional age constraints, and combining those with the sedimentological observations of Seeley (1997, 1999) and Soegaard and Callahan (1994), we hypothesize that the Hazel and Lanoria Formations represent, respectively, a proximal to distal transect of a nonmarine to marine system marginal to the Grenville/Llano deformation front (Fig. 8A).

Provenance and Age of the Van Horn Formation

The vast majority of clasts (50%–75%) present in the Van Horn Formation are felsic volcanic detritus, presumably derived from the volcanogenic formations in the west Texas area (McGowen and Groat, 1971). Zircons from the two Van Horn samples analyzed in this study further attest to input from these source regions (ca. 1.0–1.2 Ga). However, the sample collected from the upper part of the Van Horn Formation also contains mid-Cambrian-age zircons. The provenance for these zircons...
Detrital zircon geochronology of the Grenville/Llano foreland, west Texas

is somewhat problematic in that paleocurrent data (mostly southwesterly flow directions) would appear to discount the locations of Cambrian granitoids in New Mexico and Oklahoma (Amato and Mack, 2012, and references therein) as sources, hence the source of these zircons remains speculative. Nevertheless, the zircons show that at least the upper Van Horn Formation is no older than Cambrian, not Precambrian, in age. There is no obvious break between the upper and lower parts of the Van Horn Formation, thus the entire unit is likely Cambrian in age.

Zircon age spectra from the overlying Bliss Formation in southwestern New Mexico are somewhat variable, but show ca. 1.4 and 1.7 Ga peaks with some samples containing a dominant peak at ca. 505 Ma (Amato and Mack, 2012). The compiled zircon age spectra of the Bliss Sandstone are similar to that of the upper portion of the Van Horn Formation, indicating that both share a broadly similar provenance.

Depositional Model for the Van Horn Formation and Implications for the Sauk Transgression

The Van Horn Formation is interpreted to be a south-prograding alluvial fan to braided fluvial system that infilled and buried paleotopography (McGowen and Groat, 1971; Fig. 8B). This is similar in depositional style to other siliciclastic units that mark the basal Sauk Sequence such as the Mount Simon Formation in Ohio (Reuter and Watts, 2004; Leetaru and McBride, 2009), Flathead Sandstone of northern Wyoming (Bell, 1970), and Tapeats Sandstone of northern Arizona (Rose, 2006).

As originally noted by Sloss (1963), the age of the basal Sauk Sequence boundary is progressively older toward the cratonic margins. In southeast California, the lower boundary of the Sauk Sequence is either at the base of the lower member of the Wood Canyon Formation (Fedo and Cooper, 2001) or the base of the Stirling Quartzite (Hogan et al., 2011) and corresponds in age to the latest Ediacaran (see Colpron et al., 2002; Macdonald et al., 2013), post-dating the final rift event at ca. 580–560 Ma. The overlying sedimentary succession records the rift-to-drift transition along the southern margin of Laurentia, for example, and from west to east, the Zabriskie, Proveedora, Tapeats, Bolsa, Coronado, and Bliss formations (Figs. 9 and 10). This age progression is also shown by progressively younger concordant detrital zircon U-Pb ages from the western margin to the cratonic interior: the youngest concordant zircon U-Pb ages from the western margin to the cratonic interior: the youngest concordant zircon within the Wood Canyon Formation of southeast California is $524 \pm 18$ Ma (<2% discordant, 2σ, LA-ICP-MS; Stewart et al., 2001; from the geochron.org database), $521 \pm 23$ Ma for the Bolsa Formation of central Arizona ($<1\%$ discordant, 2σ, LA-ICP-MS; Stewart et al., 2001), $503 \pm 14$ Ma for the Coronado Sandstone of southeast Arizona ($<1\%$ discordant, 2σ, LA-ICP-MS; Stewart et al., 2001), and between 459 ± 23 and 468 ± 5 Ma for the Bliss Formation of southern New Mexico and west Texas ($<1\%$ discordant, 2σ, LA-ICP-MS; Amato and Mack, 2012) (Figs. 9 and 10). It should be noted that the youngest concordant zircon age determined for these units is substantiated by the bio- and lithostratigraphy throughout the basal Sauk Sequence.

Throughout the western margin of Laurentia, the majority of paleoflow directions within the Sauk Sequence are directed to the west with few exceptions (see Stewart et al., 2001; Hogan et al., 2011). However, those for the Sauk Sequence in New Mexico and west Texas display a shift from south-southeast in New Mexico and Texas to west-southwest in northern

Geological Society of America Bulletin,
Chihuahua (Mexico) and Arizona (McGowen and Groat, 1971; Stewart et al., 2001; Amato and Mack, 2012). This implies a southwest-facing paleoslope or possible topographic high along the eastern edge of the Transcontinental Arch (see Amato and Mack, 2012) during middle Cambrian time. Further, if the southern margin of Laurentia rifted later than the western one (Dalziel et al., 1994; Poole et al., 2005; Naipauer et al., 2010), an overall westward depositional slope could have been generated due to the earlier onset of differential thermal subsidence in the west.

East of the Transcontinental Arch, the basal Sauk Sequence strata are progressively older eastward (see Thomas, 1991). The three youngest detrital zircon ages from the Van Horn Formation in our study are 519 ± 10, 521 ± 6, and 522 ± 6 Ma (weighted means of <1% discordant analyses; see Fig. 7 and Table 2) and support the overall younging pattern in the maximum depositional ages of the Sauk transgression from the margin of the craton toward the interior. Additionally, in the tectonic reconstructions that place the Precordillera east of Texas (Fig. 1; Thomas and Astini, 1999), that region becomes a viable provenance as indicated by

---

Figure 9. (A) Generalized stratigraphic time-space diagram representative of the Neoproterozoic to Ordovician sedimentary units across South-central Laurentia. The ages of the youngest highly concordant detrital and rift-related igneous zircons (in Ma) are plotted as additional depositional constraints (see Table 2) (disc—discordant). In the case of the Bliss Formation, the ages of the youngest three concordant zircon analyses are plotted (from Amato and Mack, 2012). The weighted averages of multiple analyses of the youngest three zircons are plotted for the Van Horn Formation (see Fig. 7). Uncertainty is displayed at 2σ. Various rock types and general depositional settings are as per the following references: Death Valley stratigraphy—Heaman and Grotzinger (1992), Prave (1999), Corsetti and Kaufman (2003), Hogan et al. (2011); Death Valley detrital zircons—Stewart et al. (2001); Sonora stratigraphy—Stewart et al. (2002), Farmer et al. (2005), Stewart et al. (2007), Sour-Tovar et al. (2007); Grand Canyon stratigraphy—Karlstrom et al. (2000, and references therein); south-central and southeast Arizona stratigraphy—Hayes (1972); south-central and southeast Arizona detrital zircons—Stewart et al. (2001); southern New Mexico stratigraphy—Hayes (1972); southern New Mexico detrital/igneous zircons—Amato and Mack (2012); west Texas stratigraphy—Lehme (1969), Hayes (1972); west Texas detrital zircons—this study; rift-related zircons from the Wichita Mountains—Gilbert and Hogan (2010); Precordillera stratigraphy—Finney et al. (2005); Pie de Palo stratigraphy and detrital zircons—Naipauer et al. (2010); southern Appalachians stratigraphy—Tullo et al. (2010), Tull et al. (2010), Chakraborty et al. (2012); central Appalachians stratigraphy—Astini (1995), Southworth et al. (2009), Burton and Southworth (2010), Tullo et al. (2010); central Appalachians rift-related zircons—Aleinikoff et al. (1995, recalculated by Burton and Southworth, 2010), Southworth et al. (2009). Position of Sonora is restored along the Mojave megashear as per Stewart (2005) and Precordillera/Pie de Palo restored within the Ouachita embayment of Thomas (2006). Geologic time scale is after Walker et al. (2012). (B) Diagrammatic cross-section of the Sauk Sequence through central North America. Note that the datum in the section is the base of the Tippecanoe Sequence. Redrawn from Bally (1989) and Burgess (2008).
the El Quemado and El Desecho formations of the Pie de Palo region of western Argentina (Fig. 6) which have yielded concordant zircon ages of 532 ± 20 and 531 ± 31 Ma, respectively (<4% discordant) (Naipauer et al., 2010). Several rift-related igneous units exposed east of the Transcontinental Arch also provide important depositional constraints on the Sauk Sequence, such as those in the Wichita Mountains (534 ± 2 Ma; Gilbert and Hogan, 2010), the Shenandoah felsic dikes (555 ± 4 Ma and 567 ± 4 Ma; revised from Aleinikoff et al., 1995, by Burton and Southworth, 2010), and the Catocin Rhyolite (571 ± 1 Ma; Southworth et al., 2009). It is noteworthy that the timing of deposition based upon biostratigraphic studies substantiates the reliability of these ages. References for detrital zircon ages are found in the caption for Figure 9. Uncertainty is displayed at 2σ.

Figure 10. 206Pb/238U versus 207Pb/235U ages of the youngest detrital zircons from the basal units within the Sauk Sequence in southwestern Laurentia. The 1:1 line represents perfect concordance between the 206Pb/238U and 207Pb/235U ages. It is important to note that the degree of concordance is consistent with both U-Pb isotopic systems, further substantiating the reliability of these ages. References for detrital zircon ages are found in the caption for Figure 9. Uncertainty is displayed at 2σ.

CONCLUSIONS

Detrital zircon ages and depositional facies distributions in west Texas suggest that these strata respectively represent distal to proximal depositional systems in the Grenville/Llano foreland basin, respectively. Detrital zircons were primarily derived from the Llano (Grenville), Granite-Rhyolite, and Yavapai/Mazatzal provinces.

Some 400 m.y. following the Grenville orogeny and formation of Rodinia, Laurentia began rifting along its western and eastern margins (e.g., Li et al., 2008), and the consequent thermal subsidence gave rise to significant marine transgression responsible for the depth of the Sauk Sequence (Sloss, 1969). The location of the Sauk Sequence in Texas is herein redefined as the base of the Van Horn Formation, which places the timing of Sauk transgression across this part of the Laurentian craton as mid-Cambrian rather than Early Ordovician as thought previously. Both the Van Horn Formation and the overlying Cambrian Bluff Formation have similar facies characteristics and detrital zircon age distributions with a main peak at ca. 1150 Ma and other significant peaks attributable to derivation from rocks in the Oklahoma aulacogen and the Granite-Rhyolite and Yavapai/Mazatzal provinces.

ACKNOWLEDGMENTS

We thank the University of St. Andrews and Natural Environment Research Council (NERC grant NE/J021822/1) for funding support. The NERC Isotope Geosciences Facilities Steering Committee (IP-1326-0512) provided additional funding support. We would like to acknowledge Editor Nancy Riggs, Associate Editor Jeff Amato, Pat Bickford, Valbone Memetti, and two anonymous reviewers for their detailed and useful reviews of this manuscript that considerably improved clarity and style. We would also like to thank Chris Hawkesworth for helpful comments and acknowledge Darice McVay for graciously providing access to the Van Horn Formation, which is largely confined to the McVay Ranch.
