Abstract

Long noncoding RNAs (lncRNAs) are one of the most intensively studied groups of noncoding elements. Debate continues over what proportion of lncRNAs are functional or merely represent transcriptional noise. Although characterization of individual lncRNAs has identified approximately 200 functional loci across the Eukarya, general surveys have found only modest or no evidence of long-term evolutionary conservation. Although this lack of conservation suggests that most lncRNAs are nonfunctional, the possibility remains that some represent recent evolutionary innovations. We examine recent selection pressures acting on lncRNAs in mouse populations. We compare patterns of within-species nucleotide variation at approximately 10,000 lncRNA loci in a cohort of the wild house mouse, Mus musculus castaneus, with between-species nucleotide divergence from the rat (Rattus norvegicus). Loci under selective constraint are expected to show reduced nucleotide diversity and divergence. We find limited evidence of sequence conservation compared with putatively neutrally evolving ancestral repeats (ARs). Comparisons of sequence diversity and divergence between ARs, protein-coding (PC) exons and lncRNAs, and the associated flanking regions, show weak, but significantly lower levels of sequence diversity and divergence at lncRNAs compared with ARs. lncRNAs conserved deep in the vertebrate phylogeny show lower within-species sequence diversity than lncRNAs in general. A set of 74 functionally characterized lncRNAs show levels of diversity and divergence comparable to PC exons, suggesting that these lncRNAs are under substantial selective constraints. Our results suggest that, in mouse populations, most lncRNA loci evolve at rates similar to ARs, whereas older lncRNAs tend to show signals of selection similar to PC genes.

Key words: long noncoding RNAs, selection, genomics, functionality.

Introduction

Noncoding RNAs (ncRNAs), including transfer RNAs and ribosomal RNAs, are well established as key functional elements of the cellular machinery (Mattick and Makunin 2006). Recently, large-scale transcriptomics studies have revealed that a high proportion of the eukaryotic genome is transcribed, and this has led to the proposal of new classes of ncRNAs and to the addition of many new members to already existing classes. One of the most interesting classes is the long ncRNAs (lncRNAs) (Okazaki et al. 2002; Carninci et al. 2005; Mattick and Makunin 2006; Mercer et al. 2009), which are typically defined as transcribed RNA fragments exceeding a length threshold of 200 bp (Amaral et al. 2011; Brown et al. 2012; Kapusta et al. 2013). Many lncRNAs have been shown to be important regulators of gene expression (Ilik and Akhtar 2009; Rinn and Chang 2012). Increasing numbers have been predicted in various genomes, including a recent estimate of approximately 58,000 IncRNA loci in the human genome (Iyer et al. 2015). More recently, lncRNAs have been the topic of much debate concerning their functionality.

Large sets of lncRNAs and other noncoding transcripts have been identified by high-throughput genomic methods. Thousands of lncRNAs have been identified and annotated using methods such as DNA sequence tagging that indicate
5’ and 3’ transcript boundaries (Okazaki et al. 2002; Carninci et al. 2005; Pontjevic and Ponting 2007), “chromatin state maps” that reveal regions of chromatin suggestive of active transcription (Guttman et al. 2009) and, more recently, RNA sequencing (RNA-seq) to directly investigate the transcriptome (Necsulea et al. 2014). To assess the noncoding status of a region of interest, the potential for a DNA sequence to encode a protein can be assessed by a variety of algorithms (Lin et al. 2008). One example is the codon substitution frequency (CSF) metric, which assesses protein-coding (PC) potential by examining the relative frequency of synonymous and nonsynonymous codon substitutions (Lin et al. 2007).

Although little is known about the function for most identified IncRNAs, several individual loci are now known to be important in the control of gene expression, suggesting that they could constitute an important set of regulatory elements (Rinn and Chang 2012). One example is that of the Air locus in mice (Antisense Igf2r RNA), which is involved in silencing the paternal Igf2r allele in cis. Air also silences the paternal alleles of other, nearby genes (Sleutels et al. 2002; Nagano et al. 2008; Latos et al. 2012). The human homolog of Air, AirN, was found to have conserved function (Yotova et al. 2008). Another well-known example is Xist, which is involved in X-chromosome inactivation in mammals by localizing to multiple regions on the X chromosome and recruiting other molecules that repress transcription (Nesterova et al. 2001; Engreitz et al. 2013). Several other examples are detailed in table 1 of Ilk and Akhtar (2009) and in the online IncRNA database (Amaral et al. 2011; Quek et al. 2014).

The involvement of individual IncRNAs in gene regulation leads to the question of the relative importance of IncRNAs evolution and PC gene evolution to adaptation (Kapranov et al. 2007; Mercer et al. 2009; Pontjevic et al. 2009; Gutman et al. 2009; Brown et al. 2012; Kutter et al. 2012; Kapusta et al. 2013). An extreme view proposes that IncRNAs represent mostly “transcriptional noise” from an inherently stochastic transcription machinery (Pontjevic et al. 2007; Doolittle 2012). Efforts to study functionality have mostly consisted either of the detailed characterization of individual IncRNAs or surveys of large sets of IncRNAs to search for evolutionary signals indicative of function. Although initial large-scale studies found little evidence of evolutionary constraint (Okazaki et al. 2002; Wang et al. 2004; Carninci et al. 2005; Maeda et al. 2006; Pontjevic et al. 2007; Marques and Ponting 2009; Gutman et al. 2009; Derrien et al. 2012), evidence is mounting that at least some IncRNAs are conserved (Sleutels et al. 2002; Espinoza et al. 2004, 2007; Nagano et al. 2008; Yotova et al. 2008; Ilk and Akhtar 2009; Necsulea et al. 2014).

Early work on approximately 15,800 FANTOM 2 ncRNA transcripts identified in mice found that they did not differ in level of sequence conservation compared with a putatively neutrally evolving set of control sequences (Wang et al. 2004). In further analysis of the most stringently annotated set of IncRNAs from the FANTOM 2 and 3 project data sets (Okazaki et al. 2002; Carninci et al. 2005; Maeda et al. 2006; Pontjevic et al. 2007) substitution rates were found to be depressed by approximately 10% between mouse and rat, relative to putatively neutrally evolving ancestral repeat (AR) sequences (Pontjevic et al. 2007). Pontjevic et al. (2007) also found conservation in both the sequence of the ncRNAs themselves and their promoter regions (taken to be the 400 nt immediately upstream of the ncRNA transcriptional start site). Similarly, analysis of a novel set of IncRNAs identified by Guttman et al. (2009) revealed that both the sequence of the IncRNAs and promoter regions were conserved compared with random genomic fragments. Taking advantage of both the FANTOM and Guttman et al. data sets, Marques and Ponting (2009) found that substitution rates were depressed by approximately 10–12% relative to ARs. More recently, a study of approximately 9,000 human IncRNA loci from the GENCODE consortium showed higher PhastCons scores than ARs, but conservation was still substantially lower than PC loci (Derrien et al. 2012). Furthermore, derived allele frequencies in a human polymorphism data set were significantly lower at IncRNA loci than for random intergenic regions, though differences were small (Necsulea et al. 2014). However, results appear to vary across lineages: Approximately 35.8% of mutations within Drosophila melanogaster IncRNAs have been found to be weakly deleterious, whereas in Homo sapiens all mutations have been estimated to be effectively neutral, an effect that could be attributed to differences in effective population sizes (Haerty and Ponting 2013).

Here, we test for evidence of recent selection on IncRNAs using a genome-wide polymorphism data set from the wild house mouse species Mus musculus castaneus and a newly described, large data set of IncRNAs identified in the mouse genome (Necsulea et al. 2014). The house mouse represents an excellent study system for evolutionary analysis, due to its aneuploid karyotype, an extreme view proposes that lncRNAs are expected to reduce the effects of genetic drift and increase the efficacy of selection compared with species with lower Ne, such as humans (Charlesworth 2009; Phifer-Rixey et al. 2012; Haerty and Ponting 2013). Furthermore, extensive functional genomics and genetic resources are available for the mouse, which has become an important model species for functional investigation of IncRNAs.

We assess the evidence for recent purifying selection at IncRNA loci and compare the extent of selection at IncRNAs with functional loci known to be under evolutionary constraints, such as PC genes. We examine patterns of diversity in regions flanking the focal loci to investigate selection at these loci. We also examine the extent of recent purifying selection within modern wild mouse populations at IncRNA loci of varying evolutionary ages and at IncRNAs expressed in different tissue types.
Materials and Methods

In this study, we focus on a set of 10,088 mouse IncRNAs from a recent large-scale evolutionary study (Necsulea et al. 2014). This data set provides an estimate of the evolutionary age of IncRNA loci, allowing us to test for a relationship between within-species diversity and long-term evolutionary conservation. The evolutionary ages used here were determined by the phylogenetic distribution in species in which homologous sequence was detected and for which there was evidence of transcription at orthologous IncRNA loci (Necsulea et al. 2014). If homologous sequences and transcription evidence could be found across all amniotes, but not in the nonamniote species, then the age of the locus was set as the approximate age of the amniote lineage. This therefore represents a minimum estimate of the evolutionary age, because the reliable detection of transcription becomes difficult for genes that are not highly expressed and because homologous sequence identification is difficult for fast-evolving loci (Necsulea et al. 2014). Additionally, in the current data set it is possible to divide IncRNAs depending on the tissue in which they are maximally expressed, as measured by reads per kilobase per million mapped reads. Such a division might uncover selection acting on biologically important groups of IncRNAs. Finally, to partly control for potential levels of conservation at IncRNAs near protein-coding genes, IncRNAs were also grouped into intronic or intergenic IncRNAs. Intergenic IncRNAs are defined here as any IncRNA that did not overlap with an Ensembl annotation protein-coding gene.

We analyzed sequence diversity in this set of IncRNAs using the genome sequences of ten wild M. m. castaneus aligned to the NCBIM37 mm9 mouse reference genome (Halligan et al. 2013). Additionally, we examine nucleotide divergence between mouse and rat using the alignment of the mm9 mouse reference genome to the rat (rn4, Rattus norvegicus) reference genome. These alignments are available from the UCSC Genome Browser (Kent et al. 2002). We compare levels of diversity and divergence at IncRNA loci with levels at putatively neutrally evolving AR loci and evolutionarily conserved PC loci. We also investigate the patterns of diversity and divergence in the genomic regions flanking these loci to determine to what extent characteristic signals of selection are present at these loci.

To ensure that the sequences analyzed are correctly assigned to the above groups, a number of filtering steps were applied prior to analysis. The regions corresponding to the most divergent IncRNAs from the mm9–rn4 alignments were visually inspected to ensure that extreme divergence was not due to unreliable alignments, and none were rejected. We note that the use of a single rat genome as an outgroup does not allow for discrimination between diversity within rat and divergence between mouse and rat, thus we likely overestimate the extent of between-species divergence. Some IncRNAs overlap with known PC exons. To avoid confounding diversity at IncRNA loci with diversity at neighboring PC loci, a procedure for removing known elements from the data sets was carried out. Overlapping elements were always completely removed regardless of annotated strand. If neutrally evolving sites are considered in flanking regions it is possible to determine the effect of selection at a focal locus on diversity at linked neutral sites, either through genetic hitchhiking (Maynard-Smith and Haigh 1974) or through background selection (Charlesworth et al. 1993). Both of these mechanisms are expected to lead to diversity reductions at linked sites resulting in a dip around the selected site. Examining diversity in sequences surrounding
a focal site allows the identification of signals of selection (Sattath et al. 2011; Hernandez et al. 2011; Halligan et al. 2013). To this end, sites that could potentially be under selection in the flanking regions of all focal loci (PC exons, IncRNAs, and ARs) were removed as follows. At IncRNA loci, PC loci and their associated untranslated regions (UTRs) were removed, resulting in the complete removal of 51 IncRNA loci. Conserved noncoding elements (CNEs), PC exons, and UTRs were removed from flanking regions of IncRNA loci. At AR loci, PC loci, associated UTR, and IncRNA loci were removed to ensure that ARs analyzed were as far as possible neutrally evolving. CNE loci, IncRNAs, PC exons, and UTRs were removed from the flanking regions of AR loci. At PC loci and their UTRs, overlapping IncRNA loci were removed. CNEs and IncRNA loci were removed from the flanking regions of PC loci. Loci that mapped to sex chromosomes (191 loci) were excluded from the analyses, because such loci are likely to have had different selective and mutational pressures (Charlesworth et al. 1987; Baines and Harr 2007; Kousathanas et al. 2014). This resulted in a data set comprising 10,088 IncRNA loci from an initial set of 10,330.

To establish the level of evolutionary signal that can be expected from functional IncRNAs, a set of 108 well-characterized IncRNAs from the mouse were downloaded from the IncRNA database (Amaral et al. 2011; Quek et al. 2014). As some of these loci may have been selected for further experiments based on their evolutionary conservation, we note that they are potentially biased toward more conserved sequence. We used BLAT (Kent 2002) with default settings to determine the genomic positions of exons in these loci. A single best hit for each locus was chosen on the basis of highest bit score and sequence identity. Many of the entries in the database represent alternative isoforms of the same locus. If the best hit locations of two or more isoforms overlapped the same region in the mouse genome, the longest isoform was kept and the others discarded from further analysis. The final set was manually checked and ambiguously defined and overlapping loci removed. A total of 74 autosomal loci were recovered (supplementary table S1, Supplementary Material online) and analyzed as described below. Of these 74 loci of known function, the positions of 23 loci overlap with counterparts in the larger data set of 10,088. The remaining 51 are not present in our selected data set, generally due to the lack of detectable expression in the transcriptome data set used by Necsulea et al. (2014) or because they could not be unambiguously assigned to one-to-one orthologous gene families across species. In some cases, these IncRNAs were filtered out of the original data set due to overlap with annotated PC genes, or because they were classified as PC based on their CSF score or based on the presence of sequence similarity with known protein and protein domains (Necsulea et al. 2014).

Signatures of Selection
As a putatively neutrally evolving standard against which to compare the IncRNA loci, a set of ARs were used. ARs are transposable elements inserted in the genome before the split between two lineages (in this case mouse and rat) that have remained at that location. Although there are some ARs that show evidence of functionality, the available evidence suggests that the majority evolves at similar rates to that expected under neutrality (Mouse Genome Sequencing Consortium 2002; Chiaromonte et al. 2003; Lunter et al. 2006; Marques and Ponting 2009; Ózy et al. 2010; Kutter et al. 2012). Because the mutation rate, and therefore the rate of neutral evolution, varies across the genome, we examined closely linked ARs and focal loci. To this end, only AR loci within 10,000 bp up or downstream of a IncRNA locus were used in this study. Additionally, the set of all known PC exons and UTRs from the Ensembl 62 database was used as an example of loci believed to be under both negative and positive selections (Halligan et al. 2013).

Nucleotide diversity around the different genomic elements (IncRNAs, PC exons and ARs) was estimated with set of custom Python scripts from pooled, folded site frequency spectra (SFSs) across the loci. Estimating diversity and divergence from a pooled SFS across loci should reduce the effect of variation in estimates that is due short alignments. Nucleotide diversity (\(\pi\)), divergence to rat (\(d\)), \(\pi/d\), an estimate of diversity corrected for regional variation in the mutation rate, and Tajima’s D statistics were calculated for all focal loci individually and for a series of 50 nonoverlapping 1,000 nt windows upstream and downstream flanking regions of these loci (IncRNAs, PC exons, and ARs). CpG sites are known to be hypermutable in mammals and can thus lead to biases in the estimates of substitution rates if some regions are more enriched for CpG sites. Analyses were therefore carried out excluding CpG-prone sites (defined as any site either preceded by a C or followed by a G). Examining diversity in sequences surrounding a focal class of sites has previously been employed in other studies to identify signals of selection (Sattath et al. 2011; Hernandez et al. 2011; Halligan et al. 2013), because both genetic hitchhiking (Maynard-Smith and Haigh 1974) and background selection (Charlesworth et al. 1993) are expected to cause diversity reductions at linked sites resulting in a characteristic “dip” around the selected site.

Statistical Tests of Diversity and Divergence Estimates
Formal tests of differences in conservation were performed using the estimates of divergence and diversity calculated as described above. Divergence ratios (\(d_{\text{focal}}/d_{\text{neutral}}\)) measure the extent of depression in nucleotide divergence at a locus compared with a putatively neutrally evolving reference. These depressions were assessed by taking the ratio of divergence at IncRNA or PC loci to the median value for a
set of ARs, $d_{AB}$, that is, $d_{\text{occu}}/d_{\text{AB}}$, where $d_{\text{occu}}$ is the median ($d$) from the distribution of $d$ across all the focal loci (all other numbers reported below are estimates from a pooled SFS across loci). Regression models were used to investigate the relationship between evolutionary age and diversity. Two models were built for each of the diversity-related statistics (Tajima’s $D$, $\pi$, and $\pi/d$), one including a quadratic term and a linear term, and one including only a linear term. The best-fitting models were chosen by $F$-tests comparing nested models. Nonparametric 95% confidence intervals were obtained by 1,000 rounds of bootstrap sampling of the loci, allowing an unpaired two-tailed test of the degree of overlap between distributions of divergence and diversity statistics between different groups of lncRNAs and ARs. Patterns of diversity in flanking regions around focal loci can be described by nonlinear least squares models. Parameters were estimated for the equation $\pi/d \approx A \times (1 - B \times \exp(-abs(x^2)))$ where $x$ is the distance from the focal locus. The term $A$ estimates the neutral level of $\pi/d$ as $x$ tends toward infinity. The term $B$ estimates the reduction in $\pi/d$ when $x=0$. Finally, $q$ estimates the distance over which neutral levels of $\pi/d$ is recovered (Hernandez et al. 2011; Halligan et al. 2013). This model was compared with a nested model including only the term $A$ (i.e., where $B=0$) by an $F$-test which tests whether a model with a reduction in diversity closer to the focal loci is better than a model without such a reduction. All statistical tests and calculations were performed in R (R Development Core Team 2008).

## Results

Summary statistics for the data sets (and subsets) analyzed in this study are shown in supplementary tables S2–S4, Supplementary Material online. In total, 10,088 lncRNA loci (and 74 loci of known function) are considered in this study. These loci have been split on the basis of the estimated minimum evolutionary age, ranging from 370 to 12 Myr, and on the basis of expression in different tissue types (Adkins et al. 2001; Springer et al. 2004; Necsulea et al. 2014). The “mouse” group is given an age of 12 Myr, as evidence of transcription of these lncRNAs comes only from contemporary mouse populations and 12 Myr is the earliest estimated split between mouse and rat (Adkins et al. 2001; Springer et al. 2004). However, RNA-seq data for these loci are not available for rat and these loci may not all be mouse-specific. The age groups differ in the number of lncRNAs they contain, ranging from 7,306 to 62 loci, but neither the average nor the median lengths of lncRNA loci vary substantially across the different age groups (supplementary table S3, Supplementary Material online). In total, 423 loci in the data set show evidence of transcription in primates only, although homologous sequences could be identified in the mouse. These loci are included in the group of all lncRNAs, but have been excluded from the analyses of different age groups to include only the loci from different age groups that are most likely to be active in the contemporary mouse genome. Of the 22 lncRNA loci of known function that also occur in the larger data set, 12 are described as mouse-specific in the annotation of the larger data set. A further six loci are found across the Eutherian lineage and the remaining two loci across Tetrapods and across Mammals.

### Patterns of Diversity at Focal Loci

ARs show the highest level of diversity ($\pi = 0.897\%$), PC exons show the lowest level ($\pi = 0.351\%$), and the group of all lncRNAs shows a level of diversity slightly, though significantly, lower than ARs ($\pi = 0.800\%$) (table 1). Similar patterns (highest in ARs, lowest in PC exons, and an intermediate level in lncRNAs) hold for all measures of diversity and divergence ($\pi$, $d$, $\pi/d$, and Tajima’s $D$) for each age group (table 1). For all lncRNA loci, unpaired two-tailed tests indicate that there is a significant reduction for all diversity measures ($\pi$, $d$, $\pi/d$, and Tajima’s $D$) of lncRNAs compared with distributions for ARs (table 1, supplementary table S5, Supplementary Material online, all $P < 0.01$). The divergence ratio (measured as $d_{\text{occu}}/d_{\text{AB}}$) at lncRNAs is approximately 0.95 (table 1). For comparison, the divergence ratio for PC exons is 0.540 (table 1). The divergence ratio for the 74 lncRNAs of known function is also lower than that for set of all lncRNAs (0.797; table 1). Differences in diversity and divergence measures between intergenic and intronic lncRNAs are small although intronic lncRNAs did show consistently lower levels of diversity and divergence (table 1, figs. 1 and 2).

Patterns of variation in the different lncRNA age groups suggest a trend of decreasing within-species diversity with increasing age (table 2 and fig. 1). Linear regression models describing the relationship between the diversity estimates ($\pi$, $d$, $\pi/d$, and Tajima’s $D$) and evolutionary age support this trend of reduction of $\pi$, $d$, and Tajima’s $D$ with age (supplementary figs. S1–S4 and tables S6–S9, Supplementary Material online). However, this trend is marginally nonsignificant for $\pi/d$ (diversity controlled for substitution rates) (supplementary table S9 and fig. S3, Supplementary Material online). Similarly, pairwise comparisons between the bootstrap distributions of diversity and divergence measures ($\pi$, $d$, $\pi/d$ and Tajima’s $D$) for each age group and the distributions for ARs give statistical support for most differences, except in the cases of $\pi/d$ and Tajima’s $D$ (table 2). The greatest reductions in diversity ($\pi/d = 5.26$) are seen in lncRNAs common to all Tetrapods, representing about 0.6% of the total number of lncRNAs in the data set. The value of $\pi/d$ is significantly different between lncRNAs and ARs in the case of only one age group (Eutherians = 5.42 vs. ARs = 5.82, $P < 0.0001$; table 2) which represents about 16% of the total number of lncRNAs in the data set. These patterns all hold even when lncRNAs are grouped into fewer categories based on age (supplementary tables S10 and S11, Supplementary Material online).
Figure 1 also shows that confidence intervals of some diversity measures for older age groups, while overlapping with confidence intervals for ARs, also overlap the point estimates obtained for PC exons (e.g., Tetrapod lncRNAs, d, Tajima’s D; figure 1). Point estimates of π, d, Tajima’s D, and π/d for lncRNA loci of known function show substantial and statistically significant reductions when compared with ARs (table 2 and fig. 1). These estimates for
known lncRNAs are comparable to very old (~370 Myr) lncRNAs in the larger data set and also comparable to PC exons (table 2, fig. 1).

Across lncRNA loci expressed in different tissues, there are similar levels of variation in locus and exon lengths (supplementary table S4, Supplementary Material online). The number of loci reaching highest expression in each tissue type varies substantially from 234 (placenta) to 6,157 (testes). There is some variation in diversity among lncRNAs expressed in different tissue types but variation in diversity with evolutionary age is greater (tables 2 and 3, figs. 1 and 2). Statistically significant differences for all measures of diversity and divergence are found only for the numerous testis-specific lncRNAs (table 3, fig. 2). The other tissue types show mixed results with some diversity measures showing significant reductions compared with ARs. In particular, lncRNAs expressed in neural tissue show robust and statistically significant reductions in Tajima’s $D$, $\pi$ and $d$. However, none shows significant differences in $\pi/d$ (table 3 and fig. 2).

### Patterns of Diversity in Regions Flanking Focal Loci

The patterns of diversity and divergence in the regions flanking a locus can reveal the signature of selection by its effect on closely linked neutral sites. In the flanks of focal loci (lncRNA exons, PC exons and UTRs and AR loci), there is an obvious reduction only for PC exons, whereas lncRNAs and ARs show very similar patterns (fig. 3). These results hold when controlling for variation in mutation rate across the genome by normalizing by the between-species divergence ($\pi/d$; fig. 3). Patterns of diversity in regions flanking the loci are described by nonlinear least squares models. In all cases, the model describing a curve is a better description, explaining significantly more of the variation in the data, than a model including only a $y$ intercept (i.e., a straight line) (see Materials and Methods; lncRNAs $F_{(98, 199)} = 193.16$; ARs $F_{(98, 199)} = 39.43$; PC exons $F_{(98, 199)} = 439.93$; all $P < 0.01$). The parameter estimates in table 4 show that patterns of $\pi/d$ in the regions flanking lncRNAs are both quantitatively and qualitatively more similar to ARs than to PC genes. The term $A$, measuring the “background” genomic level of $\pi/d$, is, as expected, comparable across lncRNAs, ARs, and PC exons. The term $B$, measuring the reduction in $\pi/d$ as $x$ approaches 0 (i.e., closer to the focal locus), is negative and of similar magnitude in both lncRNAs and ARs, whereas it is positive and greatly reduced in PC exons (fig. 3 and table 4). However, when mouse-specific lncRNAs are removed from the data set, the nonlinear model is no longer the best-fitting model and the best prediction is a straight line with no slope and a $y$ intercept of $\pi/d$ similar to the background values of $\pi/d$ for ARs and PC exons (fig. 4 and table 4). This suggests that mouse-specific lncRNAs drive up the diversity in the overall set of lncRNAs and older lncRNAs show lower levels of diversity. Additionally Tajima’s $D$ is only markedly reduced at and around PC exons, indicating the presence of an excess of rare variants at these loci. Confidence intervals around estimates of $\pi$, $d$, $\pi/d$, and Tajima’s $D$ in the regions immediately flanking the AR and lncRNA loci mostly overlap, suggesting that there is at most a small difference in the extent of reductions in diversity and divergence at sites linked to lncRNAs and ARs (figs. 3 and 4) but that these are not significant.

### Discussion

We find a weak positive relationship between the estimated evolutionary age of lncRNAs and the level of conservation as

measured by within-species sequence diversity and between-species divergence (Fig. 1 and Table 2). These observations suggest that lncRNAs that show homology and evidence of transcription across the greatest number lineages also show reduced diversity within mice and reduced divergence from rat at the sequence level, indicative of recent selection in mouse populations. These evolutionarily most ancient loci are therefore more likely to be important...

Note.—Bootstrapped 95% confidence intervals are given in brackets. Age group-specific estimates of diversity measures with significantly different distribution of values, after a Bonferroni correction, when compared with the bootstrap distribution of ARs are denoted with * (actual P values reported in supplementary table S12, Supplementary Material online).

Fig. 3.—Divergence (d), nucleotide diversity (π), divergence-corrected nucleotide diversity (π/d), and Tajima’s D around focal loci for lncRNAs, known lncRNAs, AR and PC exons. Shaded areas indicate bootstrapped 95% confidence intervals. The panel “nlS π/d” shows fitted values from a nonlinear least squares function applied with the parameters described in table 4. The x axis has been limited to 20 kb down and upstream of the focal loci. The number of sites sampled as a function of distance is shown in supplementary figure S5, Supplementary Material online.
for fitness. Moreover, lncRNAs that have well-characterized functions also tend to be more conserved than lncRNAs in general. This is not completely unexpected, because substantial sequence conservation is often a criterion by which researchers choose targets for further study. However, considering all 10,088 lncRNAs together, there is only limited evidence for constraint at the sequence level. Although nucleotide divergence at lncRNA loci is depressed by approximately 5% compared with AR loci, the patterns of diversity around lncRNA loci seen in figures 3 and 4 do not suggest that strong selection affects variation at linked sites. There is some evidence for variation in the levels of diversity between lncRNAs expressed in different tissue types (fig. 2, table 3). Although lncRNAs specific to some tissue types show significantly lower levels of diversity in comparison to ARs, none shows levels comparable to PC exons or lncRNAs of known function. Interestingly, neural tissue-specific lncRNAs seem to be shorter, on average, than lncRNAs in general. Similar results have been found in mouse embryonic brain tissue, where lncRNAs are shorter, on average, than known lncRNAs (Lv et al. 2013). However, the shorter sequences among brain tissue lncRNAs are not likely to affect the reliability of our estimates. In general, confidence intervals are narrow indicating that the sample sizes used here are sufficient and that the limit on accuracy and sources of variation are mainly due to differing numbers of lncRNAs across groups in the analyses.

Note.—The equation applied was: $\pi/d = A \times (1 - B \times \exp(-abs(x)/q))$, where $x$ is the distance from the focal locus (in kb).
Similar findings to those detailed above have been reported for lncRNAs across the greater Tetrapod lineage, where conservation was significantly lower for lncRNA loci than random intergenic regions. Derived allele frequencies in a human polymorphism data set are significantly lower in lncRNAs than among random intergenic regions (Necsulea et al. 2014). Kutter et al. (2012) found that depressions in sequence divergence between mouse and rat were higher for lncRNA loci that show evidence of transcription in both species (~18%) than for orthologous lncRNA loci in general (~10%). Our estimates of depressions in sequence divergence, measured as divergence ratios ($d_{o} / d_{A}$), for lncRNAs compared with putatively neutrally evolving ARs are lower but comparable to the approximately 10–12% depressions found in other studies (Pang et al. 2006; Marques and Ponting 2009; Guttman et al. 2009; Kutter et al. 2012). The depressions in divergence such as those reported here and elsewhere have previously been taken as evidence of selection and functionality. When considered in combination with the patterns of diversity around the focal loci (figs. 3 and 4), and the extent of depressions in divergence around known functional lncRNA loci (~20%, table 1), the observed depressions in substitution rates of 5–12% across lncRNA loci in general are modest, suggesting that selection acting on lncRNAs is generally weak. However, some of the loci in the current data set of approximately 10,000 lncRNAs show greater evidence of reduced within-species diversity.

The most striking patterns are seen in lncRNAs that are conserved deep in the Tetrapod lineage (about 0.6% of the total set of lncRNAs). In general, lncRNAs seem to show decreasing levels of within-species sequence diversity conservation with increasing evolutionary age. Thus, our estimates of the recent selective pressures acting on lncRNAs in mouse populations are compatible with their levels of long-term evolutionary conservation. There are several potential causes of this. One explanation is that the set of older lncRNAs contains a higher proportion of functional lncRNAs. Evolutionarily old lncRNAs could be important early in tetrapod development and therefore highly conserved at the sequence level. On the other hand, these ancient loci have to be detectable across more lineages in order to be included in the older groupings and it is possible that these higher levels of conservation are partly due to an overrepresentation in these groups of more conserved sequences that can be robustly aligned across such a wide phylogenetic range. The fact that lncRNAs of known function show levels of sequence conservation comparable to older lncRNAs (e.g., tetrapod lncRNAs) suggests that the oldest groups are good candidates for further work to identify functional lncRNAs. The greater levels of sequence conservation seen at known lncRNA or functionally characterized loci also suggest that data sets of lncRNA loci identified by high-throughput sequencing and automated gene prediction are dominated by “transcriptional noise.”

The above interpretations are subject to caveats. First, previous work has shown that, in humans, lncRNA loci seem to have higher recombination rates than PC genes (Necsulea et al. 2014). If this is also the case in mice, then this could lead to increased diversity, which might degrade the signal of selection at lncRNA loci and potentially explain some of the high levels of diversity seen in this study. Second, ARs may not be evolving perfectly neutrally. If these loci are subject to some selection, then constraint will be underestimated, although the currently available evidence suggests that the neutrality of ARs is generally a reasonable assumption (Lunter et al. 2006). Similarly, constraint will also be underestimated if there is lineage-specific positive selection at a locus. Third, one view holds that a lack of sequence conservation does not necessarily indicate a lack of function (Pang et al. 2006). Empirical examples of this can be found in the experimentally characterized lncRNAs Air and Xist. These loci show relatively low levels of conservation, despite having well-established functions. At the Xist locus, significant sequence conservation across voles, mice, and human lineages is only apparent in a few regions of the full sequence of the transcribed locus, whereas most of the locus evolves at a rate similar to that of neutrally evolving loci (Nesterova et al. 2001). Additionally, a survey of conserved regions across five vertebrate genomes (human, mouse, rat, chicken, and the pufferfish) shows that only 42% of sites in a core set of ncRNA loci, some of which are lncRNAs, are part of “highly conserved elements” (Siepel et al. 2005). Controversy over the use of conservation as an indicator of function recently arose when the ENCODE project claimed to have assigned function to approximately 80% of the human genome, despite only approximately 10% being detectably conserved at the sequence level (Doolittle 2012; ENCODE Project Consortium 2012; Stamatoyannopoulos 2012; Graur et al. 2013). The conflict arises because it is unclear how a sequence can be functional in any meaningful way while not being affected by mutation (Doolittle 2012; Graur et al. 2013; Haerty and Ponting 2014). Although it seems meaningless to discuss biological function of genomic elements in the complete absence of conservation at the sequence level (Doolittle 2012; Graur et al. 2013), conservation may not be detectable in averages of diversity and divergence across entire loci. For example, conservation could be apparent only at a few nucleotides at particular positions along the length of the locus that are important for secondary structure formation, which is the case in some lncRNA loci (Diederichs 2014). lncRNAs have been found to be more folded in secondary structure than predicted by chance, albeit to a lesser extent than mRNAs, suggesting that secondary structure, rather than simple nucleotide sequence, could be under constraint (Yang and Zhang 2015). It is also possible that lncRNA loci are not constrained by nucleotide sequence directly but for sequence length or continued transcription. One interesting proposition is that simply the continued transcription of lncRNA loci is
required in order to keep chromatin open and thus facilitate the transcription of other nearby genes (Gribnau et al. 2000; Schmitt and Paro 2004; Ponjavic et al. 2007). For example, the Airn-mediated silencing of Igf2 in embryonic stem cells seems to depend only on overlap of the Aim locus with the Igf2 locus and not the transcribed product of Airn (Latos et al. 2012). Furthermore, evidence suggests that nucleotide composition within IncRNAs mirrors that of PC loci and is as low as 75% in certain regions (He et al. 2011; Schorderet and Duboule 2011). Moreover, the mouse locus has six exons and deletion of the locus in human populations and divergence from the rat at these loci and in regions flanking them to the patterns around ARs and PC exons. It was possible to group IncRNA loci by their estimated evolutionary age (as inferred by evidence of homologous sequences and transcription across different evolutionary lineages) to determine the relationship between conservation and age. In addition, a set of 74 IncRNA loci of known and characterized function in the mouse were investigated for comparison. The results suggest only modest conservation at the loci in the larger data set when compared with PC exons. There is a trend of increasing conservation with increasing age of a locus, but this trend was not strong and was not consistent across all measures of diversity. Finally, IncRNAs of known function show substantially and significantly reduced diversity and divergence when compared with neutrally evolving ARs that are comparable to PC exons. In summary, the data suggest that the majority of the IncRNAs in our data set is evolving at rates comparable to ARs at the sequence level, but that a subset show signals of selection similar to PC genes. 

Conclusions

This study focuses on previously published, large data set of approximately 10,000 IncRNAs in the mouse genome. We assessed the levels of within-species sequence diversity at these loci, in order to evaluate the recent selective pressures acting on IncRNAs and to compare them with estimates of long-term evolutionary conservation. We compared measures of sequence diversity within mouse populations and divergence from the rat at these loci and in regions flanking them to the patterns around ARs and PC exons. It was possible to group IncRNA loci by their estimated evolutionary age (as inferred by evidence of homologous sequences and transcription across different evolutionary lineages) to determine the relationship between conservation and age. In addition, a set of 74 IncRNA loci of known and characterized function in the mouse were investigated for comparison. The results suggest only modest conservation at the loci in the larger data set when compared with PC exons. There is a trend of increasing conservation with increasing age of a locus, but this trend was not strong and was not consistent across all measures of diversity. Finally, IncRNAs of known function show substantially and significantly reduced diversity and divergence when compared with neutrally evolving ARs that are comparable to PC exons. In summary, the data suggest that the majority of the IncRNAs in our data set is evolving at rates comparable to ARs at the sequence level, but that a subset show signals of selection similar to PC genes.
