Abstract

Here we describe a portable stereo camera system that integrates a GPS receiver, an attitude sensor, and 3D stereo photogrammetry to rapidly estimate the position of multiple animals in space and time. We demonstrate the performance of the system during a field test by simultaneously tracking the individual positions of 6 long-finned pilot whales, *Globicephala melas*. In shore-based accuracy trials, a system with a 50 cm stereo baseline had an average range estimation error of 0.09 m at a 5 m distance increasing up to 3.2 m at 50 m. The system is especially useful in field situations where it is necessary to follow groups of animals traveling over relatively long distances and time periods while obtaining individual positions with high spatial and temporal resolution (up to 8Hz). These positions provide quantitative estimates of a variety of key parameters and indicators for behavioural studies such as inter-animal distances, group dispersion, speed and heading. This system can additionally be integrated with other techniques such as archival tags, photo-identification methods or acoustic playback experiments to facilitate fieldwork investigating topics ranging from natural social behaviour to how animals respond to anthropogenic disturbance. By grounding observations in quantitative metrics the system can characterize fine-scale behaviour or detect changes as a result of disturbance that might otherwise be difficult to observe.

Introduction

Many animals live in groups that provide important benefits to the individual, such as decreased predation risk and lower cost of movement (Hamilton
1971; Krause and Ruxton 2002). These benefits often depend on the relative position of an individual within a group (Sumpter et al. 2008) and the behaviour of other group members (Conradt and Roper 2003; Bode et al. 2011). Realizing the benefits of a group often requires mechanisms for maintaining spatial cohesion (Krause and Ruxton 2002) and for reuniting with the group after temporary separations (Da Cunha and Byrne 2009).

Many theoretical studies have modelled how simple behaviours by individual group members with differing motivations (Conradt and Roper 2000) can give rise to remarkably complex collective movements (Gueron and Levin 1993; Parrish and Hamner 1997). These studies indicate the importance of an individual’s relative spatial position for many aspects of collective motion ranging from the impact of social networks (Bode et al. 2011) and decision-making structures (Conradt and Roper 2003; Conradt and Roper 2010) to transferring information throughout the group (Couzin et al. 2005; Sumpter et al. 2008). Until recently, empirical studies have lagged behind theory because they lacked the precision and accuracy to collect spatial data in fast-moving groups of animals (Nagy et al. 2010). However, methods have improved dramatically in recent years to the point where it is now possible to simultaneously track all members of entire groups of fish (Stienessen and Parrish 2013) or starlings (Ballerini et al. 2008; Cavagna et al. 2013) in three dimensions using fixed installations of cameras in a particular location. While these methods are extremely useful for studying animal movement and decision-processes, the fixed instrumentation limits their ability to be applied in the field to follow a group of freely moving animals over longer intervals of space and time.
Over the years, researchers have taken various approaches to estimating positions of individual animals in the field. For example, Fischhoff et al. (2007) used periodic video censuses to record the relative position of zebras during single-file travel, and King et al. (2011) observed groups of baboons from a cliff top to visually estimate individual positions and timing during movement initiation. The marine environment provides particular challenges for tracking quickly moving individuals in a group. Animals often dive out of view, and they may surface asynchronously, unpredictably, and often only for brief moments. Efforts to locate marine animals have often relied on estimating positions by eye from a distance with practicality requiring estimates to be grouped into broad spatial categories that are sampled at several minute intervals (Mattson et al. 2005). Calibrating visual observer estimates by periodically comparing them with a laser-range finder or comparing estimates to a GPS buoy such as Visser et al. (2014) did when following groups of pilot whales from 100-400m, can improve accuracy and precision. However, in general humans are often ineffective at estimating distance at sea by eye, subject to biases and large errors and with a tendency to lump measurements together (Buckland et al. 2001).

At sea, positions have been estimated by using the vertical angle between an object and the horizon (Gordon 2001), from overhead video cameras mounted on tethered airships (Nowacek et al. 2001), and by combining laser range finders with compass bearings measured with a GPS (Curé et al. 2012). Some approaches to monitoring marine animals from land can use theodolites, which measure the horizontal and vertical angles to a target (Bejder et al. 2006; Williams and Ashe 2007), but these instruments require a stable platform and they generally only
sample one individual at a time. Thus, new equipment would be helpful for studying fast-moving groups of animals in the field over longer time periods and distances.

An ideal situation would be to have the ability to obtain a quickly-updating three-dimensional position of each animal in a group. This could be accomplished by instrumenting all the animals with bio-logging systems as has been done in pigeons (Nagy et al. 2010; Flack et al. 2013; Nagy et al. 2013). However, at present, few tags have the spatial and temporal resolution required for most behavioural analyses, and tagging all group members may not always be possible.

Here we report on a portable stereo camera system that takes advantage of miniaturized digital technology to implement stereo photogrammetry for rapid and easy positioning of multiple animals. We demonstrate the performance of this system by simultaneously tracking the individual positions of 6 long-finned pilot whales, *Globicephala melas*, allowing us to estimate inter-animal distances and group dispersion as a function of time with high spatial and temporal resolution.

**System Description**

*Overview of the System*

Our portable, battery-powered system (Fig. 1) uses online stereo photogrammetry to position animals in space and time. The system integrates a GPS receiver (GPS16x, Garmin, USA) to provide camera location, an attitude sensor (3DM-GX3, Microstrain, USA) to identify the 3D direction in which the camera is aiming, and a pair of computer-controlled calibrated and synchronized stereo digital cameras (Prosilica GC 1380, Allied Vision Technologies, Canada) to measure the
range to any point in the stereo overlap area. The stereo camera is attached to an
adjustable rigid baseline and sits on a modified wildlife photography shoulder
mount (Bushhawk, USA). The centre of the stereo baseline has a sight for aiming. A
10m power and data cable connects to a 40L support cooler where a laptop running
the Ubuntu 12.04 operating system and custom software written in C controls the
data collection and processing. The entire system runs off a 12V battery. The
system’s trigger is integrated into the photography mount, and three LEDs on the
mount allow the operator to monitor whether data are being collected correctly.
Often the operator can observe contextual details during data collection that are
unavailable during analysis; therefore, a small headset microphone can be triggered
to record time-stamped voice notes, such as animal IDs, that are saved as small
audio files and synchronized with images from the camera. Although animals can
often be identified from the captured images, these notes are a particularly useful
complement with similar looking animals that may be difficult to distinguish, for
example if they are facing away from the camera.

To operate the system, the operator sights on an animal or a group of animals
and pulls the trigger in the camera mount. The LEDs signal that the system is
recording and stereo image pairs are captured at a predetermined rate of up to 8
image pairs per second. The data from the GPS and attitude sensor are recorded into
the metadata of each stereo pair. The voice recorder turns on while the trigger is
pressed, and the system continues capturing data until the trigger is released.
Battery life depends on the type of battery used as well as operating procedures: the
current configuration of a small 32 Amp-hour car battery allows 6-8h of data
collection following a group of pilot whales and recording all individual surfacings.

Technical Approach to Photogrammetric Ranging

Fig. 2 illustrates the basic principal concept of photogrammetric ranging (for
a review see Bradski and Kaehler (2008)). A pair of calibrated cameras capture a
stereo image of the target, in this case a whale fin. Lines are traced from the optical
centre of each camera through the two points in the image plane corresponding to
the same location on the target, and their intersection in the local camera reference
frame is computed using triangulation. The system computes geodetic coordinates
for the target using camera position and orientation data provided by the GPS
receiver and the attitude sensor.

System Calibration

In order to estimate range accurately, the system must take into account any
distortion in the lenses and the relative geometry of the two cameras to each other
in all six degrees of freedom (x, y, z, pitch, yaw and roll). Both of these factors were
addressed using standard stereo calibration approaches found in the OpenCV
computer vision software (Bradski and Kaehler 2008). OpenCV version 2.4 was used
for all of the analyses described in this paper. The approach uses multiple stereo
pairs of a checkerboard of known size and geometry to produce a set of calibration
matrices that map the real world system onto the idealized model illustrated in Fig.
2.
Analytical Method

Data collection produces a directory of stereo image pairs similar to the example shown in Fig. 3a. Each pair is time-stamped and includes the metadata necessary for extracting positions using our custom software. When an image pair is loaded, the software uses the calibration parameters determined previously, performs an epipolar rectification on the pair, and loads them into windows on the computer screen. Zooming in and out if necessary, the operator moves a cursor over a target in the left image (See the “Analysis Point” shown in Fig. 3a). The software then automatically cross-correlates the corresponding pixel in the right image using the Open CV matchTemplate function, a 32x32 window, and the CV_TM_CCOR_NORMED match method. Should the software fail to automatically find the correct point in the right hand image, the operator can manually choose the point.

Using the coordinates of the target point in the epipolar lines, the software computes the coordinates of the point in the camera pair coordinate system. In essence, this is a vector from the camera pair to the target. The attitude measurements extracted from the metadata are used to compute a direction cosine matrix, which is used to multiply the target vector, producing a vector in a real world (North-East-Down, or NED) coordinate system whose origin is at the camera pair.

Since the GPS based camera location has been measured and preserved in the image metadata, it can be used to convert the NED target coordinates to geodetic
coordinates. We use a scaled equirectangular projection, but given the very small
geographic area over which we make measurements in NED frame, the details of the
NED projection type do not contribute to accuracy considerations in any meaningful
way (For pseudocode of the location reconstruction algorithm, please see Online
Resource 1. The source code is available on request and can be obtained by
emailing the authors).

Coordinates of target points from the stereo images and the integrated
metadata are exported to an output file that can be easily opened in analysis
programs such as MATLAB (Mathworks, Natick, USA). When a target point is
recorded, the operator has the opportunity to apply a written label—for example, of
the animal’s ID stemming from the corresponding voice tag—that is stored with the
output. Fig. 3b shows the left hand frame of the pair shown in 3a with the whales’
geodetic latitude and longitude coordinates. Fig. 3c maps those positions into a plan
view coordinate system looking down at the water’s surface, demonstrating
example inter-animal distances at that point in time.

Accuracy Considerations

Limitations in the accuracy of this system stem primarily from errors in the
GPS position, pointing vector from the attitude sensor, and range estimated from
stereo pair images. GPS errors are well documented, and there are established
methods of filtering data for reducing them as much as possible depending on the
particular receiver used (e.g. Hide, et al. 2003; Han and Wang 2012). Pointing errors
in direction from the attitude sensor contribute to position error as a function of
distance with greater range to target leading to larger errors. The specifications of the attitude sensor used are a root-mean-square (RMS) pointing error of ±1 degree. A series of 107 measurements of a fixed sensor yielded RMS errors of 0.062, 0.035 and 0.185 degrees for pitch, roll and heading. Camera pitch and roll mostly affect altitude errors, which are not a significant concern in most marine mammal research where the targets are on the ocean’s surface; however, they could be more important if the system was used with terrestrial or airborne animals. Heading, on the other hand, is key for estimating the location of individual points. Heading error can be attributed to systematic deviation due to local magnetic fields and to inaccuracy in the heading estimate of the attitude sensor. We corrected for local geomagnetic offsets using the World Geomagnetic Model 2010; Iron errors caused by magnetic fields near the system require calibration in situ, but systematic deviation should not affect the relative location of sequential points. The attitude sensor was chosen for its high accuracy and update rate – the measured error of the heading estimate (0.2 degrees RMS) propagates into a static location error of 0.16 m RMS at 50 m, so this is negligible compared to the observed errors. Attitude measurements and image exposures occur asynchronously; the metadata for each image contains the most recent attitude measurements. This could cause time offsets between image exposures and attitude measurements, but the high update rate of the attitude sensor (typically 20 Hz) minimizes this error contribution under typical working dynamics.

Errors in stereo camera ranging stem from image errors caused by lens distortion and stereo pair based errors. Image errors are addressed by calibration,
but this will always have limits to its precision. Stereo pair based errors result from choosing slightly different points in the left and right images leading to an incorrect disparity measurement. Because estimated range is proportional to baseline divided by disparity, the system’s stereo baseline directly affects how this error is propagated through to the final measurement (Howland et al. 2012). A larger baseline reduces positioning error but also increases the minimum operating distance before a target is within the stereo overlap area. Thus, the choice of an appropriate stereo camera baseline will have to be based on considerations of typical range to target animals coupled with logistical and practical limitations on the size of equipment. We designed our system using an appropriate baseline for a target distance of up to approximately 50 m that we commonly use in focal follows. A larger baseline could easily extend the working distance.

To illustrate the range estimation accuracy of our system, we captured stereo pairs for targets located at 5 m intervals in a shore-based test using a 50 cm baseline and lenses with 25 mm focal lengths. All measurements in this paper use this baseline and focal length. Fig. 4 shows errors gradually increasing with distance from the system, ranging from an average of 0.1 m at a 5m range to 3.2 m error at a 50 m range. As with all stereo photogrammetric systems that rely on the disparity between two images in order to estimate distance, both accuracy and precision decrease with range.

When collecting data at sea in varying conditions, platform instability can be a concern. We designed our system with this in mind, using fast shutter speeds and an attitude sensor with a high-update rate to mitigate any potential effects of
movement resulting from sea state. With respect to the attitude sensor, it is not possible to completely separate gravitational acceleration from body acceleration, such as that caused by vessel motion without using a GPS-based attitude system that would be too bulky for our application; however, the sensor’s frequency-based filtering and combination of accelerometer and magnetic measurements will help minimize this error. Given this limited effect of platform instability, we used shore-based tests where it is possible to carefully measure and control all aspects of a trial to provide the most appropriate estimate of the system’s accuracy. However, to give a sense of how accuracy might change in an unstable platform, we also conducted measurement trials from a floating vessel that show similar results (Fig. 5). It is important to remember that aside from the system’s inherent accuracy, there are certainly other difficulties arising from operating in heavy seas, such as effects on the ability of those conducting the focal follow to easily see the animals; however, these would be a limitation when using almost any kind of observation technique.

**Field Test and Example Data**

We field-tested the system on a 15-minute focal follow of a group of travelling long-finned pilot whales (*Globicephala melas*) travelling in the Strait of Gibraltar. Sea state conditions were Beaufort 3-4. The group consisted of six individually-identified pilot whales, a large adult male, a female, her calf and three young adult animals of indeterminate sex. Using the stereo camera system, the position of each animal was recorded every time it surfaced, 336 measurements in total. We used the tip of the dorsal fin to define animal position because this was the
most consistently visible point. Animals were diving intermittently and did not necessarily surface at the same time, so a 2D linear interpolation was used to estimate the two-dimensional surface position of each animal between surfacings (i.e. if the animal’s position at depth was \((x,y,z)\), the projection on the surface was \((x,y,0)\). Inter-animal distances were then estimated from the interpolated surface positions of each individual. Finally, a measure of overall group dispersion was estimated as the root-mean-square (RMS) Euclidian distance between the interpolated surface position of each animal and the group centroid position. The system provides animal positions in time at each surfacing, and there are many potential ways of creating tracks beyond the linear interpolation we have used to illustrate this example.

Fig. 6a shows estimated animal tracks from these positions over a 15 min period. Tracks are shown in Northing and Easting with the initial position of the first animal as the origin. Although the animals stayed within a 150 x 250 m area, they were actually swimming steadily the entire time against a strong current. The circle, square, diamond and triangle markers super-imposed on the tracks represent individual animal positions at 3 min intervals.

We were then able to use these interpolated positions to estimate inter-animal distance over time; for example, Fig. 6b shows the distance between the mother and her calf. We described group dispersion as the RMS distance of each group member’s position to the group’s centroid at that instant in time. Note that this particular metric is linked to the number of individuals being tracked. Fig. 6b also shows estimated group dispersion over time. A higher value of dispersion
indicates an increase in spread. It was calculated using the interpolated tracks from Fig. 6a. Most animals were surfacing several times a minute, but those that were in the midst of a dive lasting 5 min or longer were excluded from the analysis in order to reduce error from linear interpolations. The same time markers used in Fig. 6a appear on Fig. 6b. A 15x speed video of overhead geodetic position with a running calculation of RMS dispersion is shown in Online Resource 2.
Discussion

We have developed a 3D stereo geocoding system that facilitates tracking multiple animals in space and time. The system is especially useful in field situations where it is necessary to track multiple animals within a group over relatively long distances and time periods while positioning individuals with high spatial and temporal resolution. The data collected can be used to calculate a variety of metrics beyond animal position; in particular, they can be used to estimate group dispersion. The system can also be easily combined with other methods such as biologging tags.

The system provides a combination of features useful for studying animals in the field, particularly in situations that require simultaneous high spatial and temporal resolution tracking of multiple individuals during a follow. First, it is portable and can be deployed from a small vehicle or research vessel. Second, it is easily aimed in any direction and does not require vessel manoeuvring to position animals in a fixed field of view. Third, it provides high spatial and temporal resolution positioning of multiple group members. As the apparent differences between Fig. 3b and 3c illustrate, estimating static positions and inter-animal distances by eye or from a fixed image is hard to do with high accuracy. Even trained visual observers are likely to judge distance in the foreshortened axis differently from the perpendicular left-right axis. Our system removes that uncertainty by providing quantitative, repeatable measurements regardless of the operator. Furthermore, while practicality often restricts behavioural observation protocols relying on human observers to a several minute sampling interval, the 8 Hz
temporal resolution of this system permits the study of finer-scale behavioural changes than may be possible to measure with observers alone. Both the spatial and temporal resolution depend on the particular configuration used, and the system is completely adjustable with baseline, cameras, lenses, sample rate, shutter speed and aperture all changeable based on the particular needs of a study. Finally, it allows multiple animals to be sampled simultaneously if captured in the same frame, or in quick succession if not.

The positions captured by the system can generate other behavioural metrics beyond the inter-animal distance illustrated in Fig. 6b. For example, different positions in time could be used to calculate a measure of speed over ground. Likewise, the geo-referenced images would allow heading to be calculated to measure any deviations that might result from environmental factors such as a disturbance (Curé et al. 2012). Even the decision about whether marine animals are associated in the same group is usually based on a definition that uses inter-animal distance as a discrimination parameter (Whitehead and Dufault 1999; Whitehead et al. 2000), so, the temporal and spatial resolution of the system could aid assessment of group size and social structure.

In particular, the ability to estimate changes in surface group dispersion over time will be useful for monitoring social behaviour, responses to predators, and the effects of disturbance. Many animals adopt social defence strategies to predators, relying on their group members to protect them (Hamilton 1971; Krause and Ruxton 2002). In the face of a threat, animals using a social defence strategy may increase social group cohesion as measured by reduced inter-animal distance (Bode
et al. 2010). Thus, dispersion is an important proxy for disturbance or stress in many species, both in connection with natural predators (Altmann 1956; Macdonald 1983; Pitman et al. 2006) as well as anthropogenic stressors such as ships and noise (Nowacek et al. 2001; Bejder et al. 2006). The continuous fine-scale estimates of dispersion that the system permits (See Fig. 6b and Online Resource 2) will aid characterization of spatio-temporal behavioural changes, be they the result of a controlled disturbance or other recorded cues.

The system can be used in tandem with a variety of other methods and behavioural data. For example, in situations where animals cannot be viewed continuously, researchers often rely on individual markings to determine individual identity. These determinations are easily recorded with the integrated vocal labelling to provide continuous tracking. Moreover, although a feature of the system is that it does not require instrumenting animals, it can be combined with bio-logging methods such as archival acoustic and kinematic tags (eg. Johnson and Tyack, 2003). In marine mammals, instrumenting animals with tags would allow the integration of surface data (e.g. the 2D illustration shown in Fig. 5a and 5b) with underwater tracks to estimate three-dimensional positions above and below the surface, in turn extending cohesion calculations and other metrics to three dimensions. Furthermore, when acoustic tags are able to identify calls from individuals or groups, the combination with the system would enable investigation of acoustic cues that might mediate any number of the fine-scale behavioural metrics the system can observe. The continuous tracking of animal location from the system could also help provide animal position with respect to other geo-referenced
environmental parameters such as topographical features, a tagged predator, an acoustic array for localizing signals, or anthropogenic disturbances.

There are many good techniques for positioning animals in space and time, and some field biologists will prefer pen and paper to a system like this whose resolution comes at the cost of purchasing and maintaining equipment and extra analysis time. We have developed our system for the field situation where multiple animals must be sampled at high spatial and temporal resolution while moving too far during the follow period to be tracked with fixed equipment installations. The system samples up to 8 times a second and allows simultaneous localization of multiple animals to distances of 50-100 m or more depending on the configuration and resolution required. These positions provide quantitative estimates of a variety of other metrics such as inter-animal distances, group dispersion, speed and heading. This system is particularly useful in combination with other techniques such as archival tags, photo-identification strategies or sound playback experiments to facilitate fieldwork investigating topics ranging from natural animal behaviour to how animals respond to anthropogenic disturbances.
Acknowledgments

This work could not have been completed without valuable contributions from many different people. We are grateful to Baxter Hutchinson and Alessandro Bocconcelli for help with the fabrication and logistics. Philippe Verborgh, Pauline Gauffier, Renaud de Stephanis, and the Center for Investigation and Research on Cetaceans (CIRCE) were essential for the fieldwork evaluating the system. This paper also benefitted from useful suggestions by two anonymous reviewers. Research was funded in part by the Office of Naval Research (grants N000140910528 and N000141210417) and the Woods Hole Oceanographic Institution Marine Mammal Center. FHJ was supported by the Danish Council for Independent Research | Natural Sciences and is currently funded by the Carlsberg Foundation. PLT was supported by the Scottish Funding Council (grant HR09011) through the Marine Alliance for Science and Technology for Scotland.
Ethical Standards

The experiments comply with Spanish and United states laws and were approved by the WHOI Institutional Animal Care and Use Committee. Fieldwork was conducted under United States National Marine Fisheries Service permit #14241 to PLT.

Notice how difficult it would be to reproduce an accurate representation of position or distance by eye alone
**Fig. 4** System accuracy at increasing range using a 50 cm baseline and lenses with 25 mm focal lengths. Five shore-based estimates were taken at 5 m intervals. a System's estimated range compared to actual range. The dotted red line represents a hypothetical perfect estimate. b Absolute error for each estimate at the intervals shown in a. The solid line is a linear best-fit through the error scores. Average deviation ranged from 0.1 m at 5 m to 3.2 m at a 50 m range. As with all stereo photogrammetric systems that rely on the disparity between two images in order to estimate distance, both accuracy and precision decrease with range.

**Fig. 5** System accuracy at increasing range measured on the water in a calm sea state (Beaufort 2). a shows absolute error of a distance measurement between 2 traffic cones placed 3 m apart (a relevant inter-animal distance) on shore at increasing ranges with the system deployed from a small unstable vessel. Assessing range for comparison with the system at sea is challenging, for even a small anchored vessel will move about, and the measurement tool used will have its own error curves. Comparison range was measured with a range-finder, but should be understood to include a range of values of +/- 3 to 4 m to account for boat movement. Distances were taken at opportunistic intervals where it was possible to stabilize the vessel as much as possible against moorings. The solid line is a linear best fit through the error scores. The average absolute value of the error ranged from 0.15 m at ~12 m up to 1.69 m at ~63 m. To get a conservative estimate of geodetic location reconstruction accuracy b shows absolute error of a geodetic
coordinate calculated using the system compared with ones measured by placing the GPS receiver on top of the target. Like a, the positions were calculated at increasing distances from a target on shore. In addition to incorporating all measurement and location reconstruction error, this plot includes both error in the system GPS and again in the GPS measurement of the target’s position without the system, leading to a conservative estimate. The solid line is a linear best fit through the error scores. Average absolute error ranged from 2.5 m at ~9 m up to 25 m at ~63 m, which is beyond the design range of a system with this baseline and focal length.

**Fig. 6 a** Interpolated tracks of animal positions of a group of 6 known long-finned pilot whales over 15 minutes. Tracks are calculated from 336 measured positions across the 6 animals. Tracks are shown in Northing and Easting with respect to the initial position of the first animal sampled. Although the animals do not appear to have travelled far, they were swimming the entire time against a strong current. The circle, square, diamond, and triangle markers represent identical points in time. **b** Dashed black line shows estimated inter-animal distance (in metres) between the mother and calf in Fig. a, calculated from 72 positions for the mother and 69 for the calf. Blue solid line shows surface cohesion of the entire group over time. Group dispersion was described as instantaneous group dispersion, defined as the RMS distance of individual positions relative to the group centroid at that instant in time. Note that this metric is linked to the number of individuals being tracked.
