1. Introduction

As part of our ongoing research programme into *programmer-in-the-loop parallelisation*, we are studying the problem of introducing alternative data structures to support parallelism. Automated support for data structure transformations makes it easier to produce the best parallelisation for some given program, or even to make parallelisation feasible. We use a refactoring approach to choose and introduce these transformations for specific *algorithmic skeletons*, structured forms of parallelism that capture common patterns of parallelism. Our approach integrates with the *Wrangler* refactoring tool for Erlang, and uses the advanced Skel [4] skeleton library for Erlang. This library has previously been shown to give good parallelisations for a number of applications, including a multi-agent system [1] where we have achieved speedups of up to 142.44 on a 61-core machine with 244 threads. We have investigated three widely-used Erlang data structures: lists, binary structures and *ETS* (Erlang Term Storage) tables. In general, we have found that *ETS* tables deliver the best parallel performance for the examples that we have considered. However, our results show that simple lists may deliver similar performance to the use of *ETS* tables, and better performance than using *binary* structures. This means that we cannot blindly choose to implement a single optimisation as part of the compilation process. Our approach also allows the use of new (possibly user-defined) data structures and other transformations in future, giving a high level of flexibility and generality.

2. Recursive Descent Refactoring

In order to transform lists into binaries or *ETS* tables, we need to define a composite refactoring. Our *recursive descent refactoring* consists of a setup phase, converting the input list xs , and a recursive phase that inspects each statement in the program, refactoring those that are relevant to xs (Fig. 1). The refactoring is designed to convert the code block that contains xs , expanding the set of terms that it looks for as xs is manipulated, and duplicating and converting any programmer-defined functions that are invoked with xs as argument. This results in an “island” of refactored functions whose interface(s) remain the same before and after refactoring (Fig. 2). Although we focus here on translating lists to binaries or *ETS* tables, the approach can be extended to either the reverse translation, or to translation to other data-types. Lists are a primitive data-type in Erlang that can contain potentially infinite elements of any type. Lists are *copied* when they passed between processes, and can be

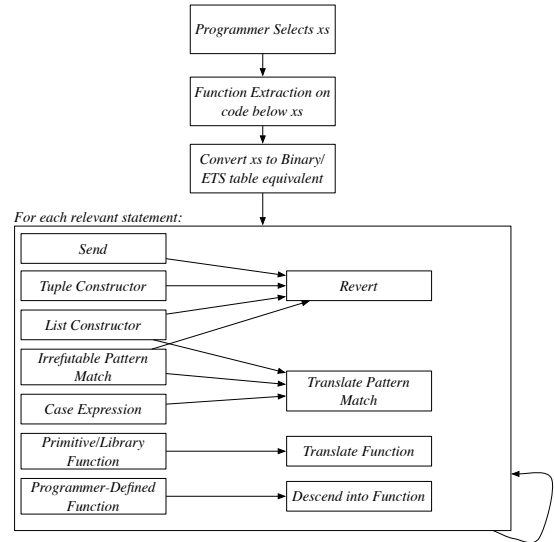

Figure 1. Recursive Descent Refactoring Approach

Figure 2. Result of applying recursive descent refactoring.

slow when randomly accessing elements. Erlang *binaries* have a similar syntax to lists, but have more numerous options during construction and pattern matching, where the type and size of individual elements can be specified. Binaries that are larger than 64 bytes are not copied between process heaps, but instead are passed by reference. They are also useful, and sometimes necessary, when interfacing both with GPUs and with other programming languages. Finally, *ETS* tables are global, mutable term storage providing constant access time to the contained data. There are four types of *ETS* table and a range of construction options.

3. Illustrative Example: Image Merge

Image Merge takes a list of pairs of images (each represented as a two-dimensional list), and merges each pair. The main computation is defined by the `convertMerge/1` function.

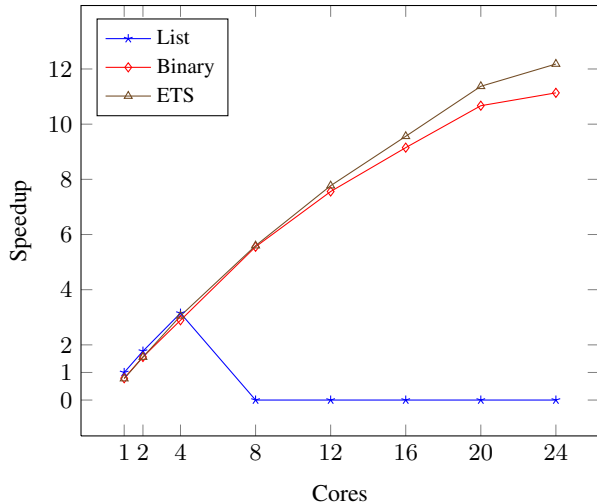

Figure 3. Speedups for Image Merge on *Titanic*

```

convertMerge({Xs, Ys, F1, F2, Name}) ->
  Xs_p = lists:map(
    fun(L) ->
      removeAlpha(L, F1)
    end, Xs),
  Ys_p = lists:map(
    fun(L2) ->
      removeAlpha(L2, F2)
    end, Ys),
  WhiteR = lists:map(
    fun(Col) ->
      convertToWhite(Col)
    end, Xs_p),
  Result = lists:zipwith(
    fun(L1, L2) ->
      mergeTwo(L1, L2)
    end, WhiteR, Ys_p),
  {Result, length(Xs), Name}.

```

There are two refactoring opportunities. Both Xs and Ys are lists. We might choose either, or both, of these to translate into either an ETS or binary equivalent. When performed as a combination of a task farm and a two-stage pipeline, transmitting images between processes can result in significant memory usage. Indeed, this problem presented itself during testing on large numbers of images. This alone provides significant motivation to use our recursive descent refactoring to translate both Xs and Ys . When merging 100 pairs of 1024x1024 images, we observe that both the binary and ETS representations avoid the excessive memory usage of the list representation. Our experiments were performed on *Titanic*, a 2.3GHz AMD Opteron 6176 machine with 24 physical cores and 32 GB of RAM at the University of Pisa. Each experiment was repeated 10 times and we recorded the mean result. Fig. 3 gives speedups for varying number of cores compared with the original list sequential version. We observe a maximum speedup of 12.2 for the ETS representation, and 11.1 for the binary representation, where the original list sequential version takes on average 600, 211, 668.4 μ s, or 10.0035 minutes. The slight advantage for the ETS version could be because the built-in fold operation, which the ETS map operation uses, is more efficient than the recursive function that is defined for binaries.

4. Related Work

Numerous and varied approaches have previously been proposed to simplify the introduction and management of parallelism. While fully automatic approaches benefit not requiring programmer involvement, they are also limited by the language(s) they work on,

and by the transformations they can perform. Existing tools and techniques that are designed to simplify restructuring [1] primarily focus on involving the programmer in decision making, whilst performing menial tasks automatically. These include interactive parallelisation tools such as [3], and previous refactoring techniques applied to parallelism [2, 4]. Current demonstrations of this approach have been limited to refactorings that focus on re-arranging and abstracting patterns from existing code. Even when the program types themselves are targets for the refactoring [6], a *change* of data-type for the data being manipulated is not considered.

5. Conclusions and Future Work

The correct choice of data structure can make a significant difference to parallel performance. To date, this has been generally a manual process. We have discussed a new type-translation refactoring that is designed to automatically translate Erlang list structures and operations to equivalent binary and ETS forms and applied our approach to the image example, implemented using the Skel parallel skeleton library for Erlang. For this example, our results show that ETS tables clearly deliver the best parallel performance: significantly better than lists and about 10% better than binaries. Whilst our results might therefore lead us to conclude there is little reason to use binaries, and that all lists should potentially be translated into ETS tables, this would be premature. As demonstrated in [5], binaries are required when interfacing with other languages and hardware, e.g. OpenCL and GPUs. Furthermore, both lists and binaries can be passed across distributed systems with less administrative overhead than ETS tables, nor do they present a natural bottleneck with high frequency accesses across processes as with ETS tables. We therefore instead conclude that the correct choice of data-type is highly dependent upon the specific parallel program and its context, and should not be left to a blind optimisation process as part of a compilation phase.
